### Biographies

**Dr Puneet Opal MD, PhD** is an Associate Professor of Neurology at Northwestern University Feinberg School of Medicine. He holds additional faculty appointments in the department of Cell and Molecular Biology and Interdepartmental Program in Neuroscience. At Northwestern Memorial Hospital, Dr. Opal runs a neurological practice focusing on movement disorders and disorders of the cerebellum. In addition, Dr. Opal heads a research laboratory dedicated to understanding neurodegenerative diseases. His current focus is on elucidating the molecular mechanisms underlying genetic movement disorders.

**Dr Huda Y Zoghbi, MD, PhD** is Professor of Pediatrics, Neurology, Neuroscience, and Molecular and Human Genetics at Baylor College of Medicine and serves as an Investigator with the Howard Hughes Medical Institute. She is also the Director of the Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital. Dr. Zoghbi's research focuses on elucidating the pathogenesis of dominantly inherited Spinocerebellar ataxia type 1 and childhood autism spectrum disorders including Rett syndrome.

## Hereditary Spastic Paraplegia

John K Fink

Department of Neurology, University of Michigan and Geriatric Research Education and Care Center,  
Ann Arbor Veterans Affairs Medical Center, Ann Arbor, MI, USA

### 119.1 INTRODUCTION

The hereditary spastic paraplegias (HSPs) are a clinically and genetically diverse group of disorders in which the predominant symptom is lower extremity weakness and spasticity that usually, though not always, progresses insidiously. HSP is also referred to as familial spastic paraplegia (FSP), hereditary (or familial) spastic paraparesis, and Strümpell–Lorrain syndrome (1).

This chapter summarizes clinical features including diagnosis, classification, differential diagnosis, treatment and counseling, HSP-related disorders, complicated HSP syndromes, and advances in our understanding of the molecular genetic basis of HSP. For previous review of HSP and early descriptions see (2).

#### 119.1.1 History

The earliest reports of HSP were those of Seeligmüller in 1876 (3), who described a family with progressive spastic weakness of the lower extremities. Subsequently, Strumpell in 1880 and Lorraine in 1898 (4) described families with hereditary progressive lower extremity spastic weakness in the absence of other neurologic abnormalities (1,5,6).

#### 119.1.2 Ethnicity

HSP kindreds have been described from diverse geographic and ethnic backgrounds including European (Belgian, Dutch, English, Icelandic, Irish, Italian, French, German, Greek, Norwegian, Portuguese, Romanian, Spanish, Swedish, Swiss, Turkish), South American (Brazilian and Columbian), Asian (Chinese, Japanese, Korean, Tibetan), Middle Eastern (Egyptian, Jordanian, Iraqi, Israeli), Australian, and Indian ancestry. Although there are relatively few reports of HSP kindreds of African descent (7), HSP has been described in many Tunisian kindreds, in a South African Zulu family (8), and in a family from Mali (9).

#### 119.1.3 Prevalence

The prevalence of HSP has been estimated to be 1.27 in Ireland (10), 2.7 per 100,000 in Italy (11), 5.75 per

100,000 in Tunisia (Sfax district) (12), 7.4 per 100,000 in Norway (13), and 9.6 per 100,000 in Spain (14). In Norway, the prevalence of autosomal dominant HSP (5.5 per 100,000) exceeded that of autosomal recessive HSP (0.6 per 100,000) and isolated cases of spastic paraplegia (1.3 per 100,000) (13).

#### 119.1.4 Genetic Classification

HSP is classified genetically according to the mode of inheritance (autosomal dominant, autosomal recessive, and X-linked HSP). Genetic loci for HSP are designated “SPG” and numbered one through 48 in order of their discovery (Table 119-1). In addition, several genetic types of HSP have been reported, which do not have SPG loci designations (e.g., SPOAN syndrome and mitochondrial ATP6 gene mutation, Table 119-1).

#### 119.1.5 Clinical Classification

Historically, HSP clinical syndromes have been classified (56) as “uncomplicated” (also referred to as “pure” or “non-syndromic” HSP) if neurologic deficits are limited to progressive lower extremity spastic weakness, hypertonic urinary bladder disturbance (57), and often, but not always, mild diminution of lower extremity vibration sensation. HSP is classified as “complicated” (“syndromic”) if, in addition to the impairments present in “uncomplicated” HSP, the *heritable syndrome includes other neurologic or systemic abnormalities that are not attributable to alternative or coexisting disorders*. Thus, “complicated HSP” is characterized by insidiously progressive lower extremity weakness and spasticity, accompanied by such neurologic or systemic impairments as seizures, mental retardation, dementia, cataracts, amyotrophy, optica atrophy, ataxia, extrapyramidal disturbance, cutaneous abnormalities, or peripheral neuropathy.

As noted below, there is imperfect correlation of HSP clinical syndromes with specific genetic types of HSP. Increasingly, it is recognized that a given genetic type of HSP (including the most common dominant and

TABLE 119-1 Genetic Types of HSP

Spastic Gait (SPG) Locus	Clinical Syndrome	Protein	Gene Testing	References
<b>Autosomal dominant HSP</b>				
SPG3A (14q11-q21)	Uncomplicated HSP: symptoms usually begin in childhood (and may be nonprogressive); symptoms may also begin in adolescence or adulthood and worsen insidiously. Genetic nonpenetrance reported. <i>De novo</i> mutation reported. Presenting as spastic diplegic cerebral palsy	Atlastin	ADL	(15–17)
SPG4 (chr.2p22)	Uncomplicated HSP, symptom onset in infancy through senescence, single most common cause of autosomal dominant HSP (~40%); some subjects have late-onset cognitive impairment	Spastin	ADL <sup>a</sup>	(18–22)
SPG6 (15q11.1)	Uncomplicated HSP: prototypical late-adolescent, early-adult-onset, slowly progressive	"Not imprinted in Prader Willi/Angelman 1" (NIPA1)	ADL	(23–26)
SPG8 (8q23-q24)	Uncomplicated HSP	KIAA0196/Strumpellin	ADL	(27–31)
SPG9 (10q23.3-q24.2)	Complicated: spastic paraplegia associated with cataracts, gastroesophageal reflux, and motor neuronopathy	Unknown	No	(32,33)
SPG10 (12q13)	Uncomplicated HSP or complicated by distal muscle atrophy	Kinesin heavy chain (KIF5A)	Lab	(34,35)
SPG12 (19q13)	Uncomplicated HSP	Unknown		(28)
SPG13 (2q24-34)	Uncomplicated HSP: adolescent and adult-onset	Chaperonin 60 (also known as heat shock protein 60, HSP60)	Lab	(36–38)
SPG17 (11q12-q14)	Complicated: spastic Paraplegia associated with amyotrophy of hand muscles (Silver syndrome)	BSCL2/seipin	Lab	(39–41)
SPG19 (9q33-q34)	Uncomplicated HSP	Unknown	No	(42)
SPG29 (1p31.1–21.1)	Complicated: spastic paraplegia associated with hearing impairment; persistent vomiting due to hiatal hernia inherited	Unknown	No	(43)
SPG31 (2p12)	Uncomplicated HSP or occasionally associated with peripheral neuropathy	Receptor expression enhancing protein 1 (REEP1)	ADL	(44–46)
SPG33 (10q24.2)	Uncomplicated HSP	ZFYVE27/protrudin}	Lab	(47)
SPG36 (12q23-24)	Onset age 14–28 years, associated with motor sensory neuropathy	Unknown	No	(48)
SPG37 (8p21.1-q13.3)	Uncomplicated HSP	Unknown	No	(49)
SPG38 (4p16-p15)	One family, five affected subjects, onset age 16–21 years. Subjects had atrophy of intrinsic hand muscles (severe in one subject at age 58)	Unknown	No	(50)
SPG40 (locus unknown)	Uncomplicated spastic paraplegia, onset after age 35, known autosomal dominant HSP loci excluded	Unknown	No	(51)
SPG41 (11p14.1-p11.2)	Single Chinese family with adolescent-onset, spastic paraplegia associated with mild weakness of intrinsic hand muscles	Unknown	No	(52)
SPG42 (3q24-q26)	Uncomplicated spastic paraplegia reported in single kindred, onset age 4–40 years, possibly one instance of incomplete penetrance	Acetyl CoA transporter (SLC33A1)	No	(53–55)
<b>Autosomal recessive HSP</b>				
SPG5 (8p)	Uncomplicated or complicated by axonal neuropathy, distal or generalized muscle atrophy, and white matter abnormalities on MRI	CYP7B1	Lab	(123,418,419, 473, 497–500)
SPG7 (16q)	Uncomplicated or complicated: variably associated with mitochondrial abnormalities on skeletal muscle biopsy and dysarthria, dysphagia, optic disc pallor, axonal neuropathy, and evidence of "vascular lesions," cerebellar atrophy, or cerebral atrophy on cranial MRI	Paraplegin	ADL et al	(155,239)

**TABLE 119-1 Genetic Types of HSP—cont'd**

SPG11 (15q)	Uncomplicated or complicated: spastic paraplegia variably associated with thin corpus callosum, mental retardation, upper extremity weakness, dysarthria, and nystagmus; may have "Kjellin syndrome": childhood-onset, progressive spastic paraplegia accompanied by pigmentary retinopathy, mental retardation, dysarthria, dementia, and distal muscle atrophy; juvenile, slowly progressive ALS reported in subjects with SPG11 HSP; 50% of autosomal recessive HSP is considered to be SPG11	Spatacsin (KIAA1840)	Lab	(169,501,502)
SPG14 (3q27-28)	Single consanguineous Italian family, three affected subjects, onset age ~30 years. Complicated spastic paraplegia with mental retardation and distal motor neuropathy (sural nerve biopsy was normal)	Unknown	No	(267)
SPG15 (14q)	Complicated: spastic paraplegia variably associated with associated with pigmented maculopathy, distal amyotrophy, dysarthria, mental retardation, and further intellectual deterioration (Kjellin syndrome)	Spastizin/ZFYVE26	Lab	(258,259)
SPG18 (8p12-p11.21)	Two families described with spastic paraplegia complicated by mental retardation and thin corpus callosum	Unknown	No	(503)
SPG20 (13q)	Complicated: spastic paraplegia associated with distal muscle wasting (Troyer syndrome)	Spartin	Lab	(264,266,275, 428,471)
SPG21 (15q21-q22)	Complicated: spastic paraplegia associated with dementia, cerebellar and extrapyramidal signs, thin corpus callosum, and white matter abnormalities (Mast syndrome)	Maspardin	Lab	(162)
SPG23 (1q24-q32)	Complicated: childhood-onset HSP associated with skin pigment abnormality (vitiligo), premature graying, characteristic facies; Lison syndrome	Unknown	No	(263)
SPG24 (13q14)	Complicated: childhood-onset HSP variably complicated by spastic dysarthria and pseudobulbar signs	Unknown	No	(504)
SPG25 (6q23-q24.1)	Consanguineous Italian family, four subjects with adult (30–46 years) onset back and neck pain related to disk herniation and spastic paraplegia; surgical correction of disk herniation ameliorated pain and reduced spastic paraplegia. Peripheral neuropathy also present	Unknown	No	(505)
SPG26 (12p11.1–12q14)	Single consanguineous Bedouin family with five affected subjects. Complicated: childhood onset (between 7 and 8 years), progressive spastic paraparesis with dysarthria and distal amyotrophy in both upper and lower limbs, nerve conduction studies were normal; mild intellectual impairment, normal brain MRI	Unknown	No	(271)
SPG27 (10q22.1-q24.1)	Complicated or uncomplicated HSP. Two families described. In one family (seven affected subjects) uncomplicated spastic paraplegia began between ages 25 and 45 years. In the second family (three subjects described) the disorder began in childhood and included spastic paraplegia, ataxia, dysarthria; mental retardation, sensorimotor polyneuropathy, facial dysmorphism and short stature	Unknown	No	(32,256)
SPG28 (14q21.3-q22.3)	Uncomplicated: childhood-onset progressive spastic gait	Unknown	No	(506)
SPG29 (14q)	Uncomplicated HSP, childhood onset	Unknown	No	(507)

Continued

**TABLE 119-1 Genetic Types of HSP—cont'd**

SPG30 (2q37.3)	Complicated: spastic paraplegia, distal wasting, saccadic ocular pursuit, peripheral neuropathy, mild cerebellar signs	Unknown	No	(508)
SPG32 (14q12-q21)	Mild mental retardation, brainstem dysraphia, clinically asymptomatic cerebellar atrophy	Unknown	No	(509)
SPG35 (16q21-q23)	Childhood onset (6–11 years), spastic paraplegia with extrapyramidal features, progressive dysarthria, dementia, seizures. Brain white matter abnormalities and brain iron accumulation; an Omani and a Pakistani kindred reported	Fatty acid 2-hydroxylase (FA2H)	Lab	(160,161,510)
SPG39 (19p13)	Complicated: spastic paraplegia associated with wasting of distal upper and lower extremity muscles	Neuropathy target esterase (NTE)	Lab	(273)
SPG43 (19p13.11-q12)	Two sisters from Mali, symptom onset 7 and 12 years, progressive spastic paraplegia with atrophy of intrinsic hand muscles and dysarthria (one sister)	Unknown	No	(9)
SPG44 (1q41)	Allelic with (PMLD, early-onset dysmyelinating disorder with nystagmus, psychomotor delay, progressive spasticity, ataxia). GJA/GJC2 mutation I33 M causes a milder phenotype: late-onset (first and second decades), cognitive impairment, slowly progressive, spastic paraplegia, dysarthria, and upper extremity involvement. MRI and MR spectroscopy imaging consistent with a hypomyelinating leukoencephalopathy	Gap junction protein GJA12/GJC2, also known as connexin47 (Cx47)		(290)
SPG45 (10q24.3-q25.1)	Single consanguineous kindred from Turkey, five subjects described: affected subjects had mental retardation, infantile onset lower extremity spasticity and contractures, one subject with optic atrophy, two subjects with pendular nystagmus; MRI in one subject was normal	Unknown	No	(511)
SPG46 (9p21.2-q21.12)	Dementia, congenital cataract, ataxia, thin corpus callosum	Unknown	No	(512)
SPG47 (1p13.2-1p12)	Two affected siblings from consanguineous Arabic family with early childhood-onset slowly progressive spastic paraparesis, mental retardation, and seizures; one subject had ventriculomegaly, the other subject had thin corpus callosum and periventricular white matter abnormalities	Unknown	No	(513)
SPG48 (7p22.1)	Analysis of KIAA0415 gene in 166 unrelated spastic paraplegia subjects (38 recessive, 64 dominant, 64 “apparently sporadic”) and control subjects revealed homozygous mutation in two siblings with late-onset (6th decade) uncomplicated spastic paraplegia; and heterozygous mutation in one subject with apparently sporadic spastic paraplegia	KIAA0415	Lab	(316)
“SPOAN” syndrome (11q23)	Complicated: Spastic paraplegia, optic atrophy, neuropathy (SPOAN)	Unknown	No	(118)
5p15.31-14.1 No SPG designation	Complicated spastic paraplegia associated with mutilating sensory neuropathy	Epsilon subunit of the cytosolic chaperonin-containing t-complex peptide-1 (Cct5)	Lab	(119,450)
<b>X-linked HSP</b>				
SPG1 (Xq28)	Complicated: associated with mental retardation, and variably, hydrocephalus, aphasia, and adducted thumbs	L1 cell adhesion molecule (L1CAM)	Lab	(151)
SPG2 (Xq28)	Complicated: variably associated with MRI evidence of CNS white matter abnormality; may have peripheral neuropathy	Proteolipid protein (PLP)	Several labs <sup>b</sup>	(514–517)

**TABLE 119-1 Genetic Types of HSP—cont'd**

SPG16 (Xq11.2-q23)	Uncomplicated; or complicated: associated with motor aphasia, reduced vision, nystagmus, mild mental retardation, and dysfunction of the bowel and bladder	Unknown	No	(277,278)
SPG22 (Xq21)	Complicated (Allan–Herndon–Dudley syndrome): congenital onset, neck muscle hypotonia in infancy, mental retardation, dysarthria, ataxia, spastic paraplegia, abnormal facies	Monocarboxylate transport 8 (MCT8)	Lab	(518–520)
SPG34	Uncomplicated, onset 12–25 years			(521)
Maternal (mitochondrial) inheritance HSP				
No SPG designation	Adult-onset, progressive spastic paraplegia, mild to severe symptoms, variably associated with axonal neuropathy, late-onset dementia, cardiomyopathy.	Mitochondrial ATP6 gene	Lab	(212)

Source: Updated from (522).

recessive forms) may manifest as both “complicated” and “uncomplicated” HSP syndromes.

Previously, Harding (56) proposed subclassifying autosomal dominant, uncomplicated HSP according to the age-of-symptom onset, the relative degrees of spasticity and weakness, and the rate of progression. According to this scheme, individuals with autosomal dominant uncomplicated HSP Type I had symptom onset before the age of 35, greater lower extremity spasticity than weakness, and slow progression. Individuals with type II uncomplicated HSP had symptom onset after age 35, significant lower extremity weakness in addition to spasticity, mild distal sensory loss, urinary bladder disturbance, and faster progression (56,58). Classification based on age-of-symptom onset is problematic because the age-of-symptom onset may be extremely variable even within a given family. We (59) and others (60,61) have observed HSP kindreds in which some family members developed symptoms in childhood and others in late adulthood, consistent with both Type I and Type II occurring within the same family. Furthermore, although *average* age-of-symptom onset in some forms of HSP is earlier (e.g., SPG3A, SPG10, SPG12) than others (SPG4, SPG6, SPG8, and SPG13), there is significant overlap in the *range of ages* at which symptoms first appear between “early” and “later” onset HSP (Table 119-2) (62). For these reasons, HSP is not classified by age-of-symptom onset alone.

*Complicated HSP syndromes* are those in which the heritable syndrome is predominated by insidiously progressive, bilaterally symmetric, lower extremity spastic weakness and accompanied by additional systemic or neurologic abnormalities (which are part of the heritable syndrome and not due to coexisting neurologic disorders). Spastic weakness in the legs of mild to severe degree is a feature of many unrelated neurologic syndromes that are not considered “complicated HSP.” For example, Machado–Joseph disease, early-onset familial Alzheimer’s disease due to presenilin 1 gene mutation, (63) and amyotrophic lateral sclerosis (ALS) may all have lower extremity spastic weakness, yet none are

considered “complicated HSP.” Diagnosis of uncomplicated or complicated HSP requires progressive lower extremity spastic weakness to be *the predominant clinical feature*; and the *exclusion (by clinical evaluation, laboratory studies, electromyography, nerve conduction testing, and neuroimaging) of alternative disorders*.

The “complicated spastic paraplegia” classification includes many diverse syndromes (Table 119-1) that undoubtedly represent many etiologically distinct disorders. In general, genetic analysis of complicated HSP syndromes has been hampered by the small size of individual families and by the likelihood of genetic heterogeneity. In addition to the syndromes listed (Table 119-1), there are many case reports of HSP associated with other systemic disorders (64–68), neurologic syndromes (e.g., restless leg syndrome (69), Parkinson’s (70), and ALS (71)). For individual kindreds of limited size, it is often uncertain whether two unrelated disorders simply coexist in the family such as HSP and epilepsy (72) or HSP and cardiac abnormalities (73); or whether the extra-spinal abnormalities are variant manifestations of HSP.

**119.1.5.1 Imperfect Correlation between Clinical and Genetic Classifications.** Classifying the clinical syndrome in an individual subject or family as “complicated HSP” or “uncomplicated HSP” is useful in terms of diagnostic recognition of the HSP syndrome, prognosis, and genetic counseling. Nonetheless, it is important to recognize that there is imperfect agreement between genetic and clinical classifications. For example, while some subjects with SPG7 autosomal recessive HSP (due to paraplegin gene mutation) and SPG10 HSP (due to kinesin heavy chain mutation) have uncomplicated HSP, other subjects with these types of HSP have complicated HSP syndromes (compare, e.g., descriptions of “uncomplicated” (74) and “complicated” (75)) SPG10 HSP due to KIF5A mutation; and complicated and uncomplicated forms of SPG7 HSP due to paraplegin mutation (76–79).

For an individual subject and their affected family members, the certainty of determining that an HSP syndrome is “uncomplicated” or “complicated” often

depends on the nature and extent of diagnostic evaluations (e.g., were nerve conduction studies and formal neuropsychometric studies performed in every subject?); and the extent of long-term, serial evaluation to observe the natural history of the disorder. Similarly, determining that an individual genetic type of HSP is always (e.g., 100%), usually (e.g., 50–100%), sometimes (e.g., 25–50%), occasionally (e.g., 10–25%), rarely (<10%), or never (0%) associated with either “uncomplicated” or “complicated” syndromes depends on long-term, serial evaluation of many individuals from ethnically diverse, unrelated families using detailed and standardized methods. With the exceptions of SPG1, SPG2, SPG3A, SPG4, SPG7, and SPG11, descriptions of most HSP types have been limited to one or several kindreds. Therefore, the phenotypic spectrum of most types of HSP must be considered incompletely known.

Rather than rigidly classifying a given type of HSP as “complicated” or “uncomplicated”, it is increasingly evident that various genetic forms of HSP are more *reliably* classified as *typically associated with uncomplicated HSP*, *variably associated with complicated HSP* (i.e., being associated with either uncomplicated or complicated HSP), *and typically associated with complicated HSP*. As this knowledge is unfolding, the certainty that a given type of HSP is “typically uncomplicated,” “variably complicated,” or “typically complicated” should consider the published number, size, and extent of evaluation of individuals and families with this type of HSP. Particular caution must be exercised (1) in too readily ascribing a variant neurologic or systemic symptom as representing a “complicated” feature of HSP (rather than investigating the symptom directly for alternative causes); (2) assuming that

**TABLE 119-2    Complicated HSP Syndromes<sup>a</sup>**

<b>Spastic Paraplegia and Peripheral Neuropathy</b>	
HSP types SPG2, 3A, 5, 7, 10, 25, 27, 30, 31, SPOAN, Cct5 (epsilon subunit), mutation, mitochondrial ATP6 gene mutation	See Table 119-1 and text for references
Spastic paraplegia, neuropathy, poikiloderma; autosomal dominant	(523)
Spastic paraplegia and peripheral neuropathy; autosomal dominant	(524)
Spastic paraplegia, early-onset painless perforating and mutilating ulcers of the hands and feet. Loss of pain and of the sensations of touch, heat, and cold over the feet. Shooting pains in the legs, and occasionally in arms. Probably autosomal recessive	(122,525)
Spastic paraplegia and sensory neuropathy with mutilating ulcerations of the hands and feet. Possibly autosomal dominant	(526)
Early onset of paraparesis (first decade), peripheral neuropathy, depigmented areas of skin and hair. Probably autosomal recessive	(527)
Spastic paraplegia, mental retardation, distal motor neuropathy. Autosomal recessive	(267)
<b>Spastic paraplegia and distal amyotrophy</b>	
HSP types SPG3A (rare feature of), 4 (rare feature of), 5, 10, 14, 15, 17, 20, 26, 30, 38, 39, 41, 43	See Table 119-1 and text for references
Spastic paraplegia, onset in the second decade with slight progression, normal life span, amyotrophy of the hands; autosomal dominant	(525)
Spastic paraparesis with distal muscle wasting, microcephaly, mental retardation, arachnodactyly, tremor; autosomal recessive	(528)
Spastic paraplegia with peroneal amyotrophy and fever-induced episodes of pain, dysethesia, tetraparesis; autosomal recessive	(529)
Spastic paraplegia (nonprogressive, infantile onset), distal muscle wasting, mental retardation, short stature; probably autosomal recessive	(530)
Spastic paraplegia, mental retardation, distal motor neuropathy; autosomal recessive	(267)
<b>Spastic paraplegia and mental retardation</b>	
HSP types SPG 1, 11, 14, 16, 18, 20, 22, 26, 27, 32, 44, 45, 47	See Table 119-1 and text for references
Spastic paraplegia with glaucoma and mental retardation; probably autosomal recessive	(531)
Spastic paraplegia, dysarthria, ataxia, mental retardation, pigmentary macular degeneration; probably autosomal recessive	(532)
Mental deficiency and spastic paraplegia; autosomal recessive	(533)
Spastic paraplegia (nonprogressive, infantile onset), distal muscle wasting, mental retardation, short stature; probably autosomal recessive	(530)
Spastic paraparesis (childhood onset), dysarthria, mental retardation, cerebellar ataxia, tremor, and periventricular white matter abnormalities; probably X-linked	(534)
Spastic paraplegia, mental retardation, precocious puberty; autosomal recessive	(535)
Spastic paraplegia, mental retardation, distal motor neuropathy	(267)
<b>Spastic paraplegia and dementia</b>	
SPG4, 15, 21, 35, 46, and Mitochondrial ATP6 gene mutation	
Spastic paraplegia, dementia, cardiac abnormalities; autosomal recessive	(73)
Adult-onset-HSP dementia and thalamic degeneration; autosomal dominant	(536)

**TABLE 119-2    Complicated HSP Syndromes<sup>a</sup>—cont'd**

<b>Spastic paraplegia and blindness</b>	
HSP types SPG15, 16, 45, 46, and SPOAN syndrome	See Table 119-1 and text for references
Spastic paraplegia with retinal degeneration; autosomal recessive	(537)
Spastic paraplegia, optic atrophy, dementia; autosomal dominant	(538)
Bilateral hypoplasia of the optic nerve. Pupillary light-near dissociation, peripheral neuropathy, fasciculations, cardiomyopathy	(539)
Spastic paraplegia, dysarthria, ataxia, mental retardation, pigmentary macular degeneration; probably autosomal recessive	(532)
Spastic paraplegia, mental retardation, amyotrophy, pigmentary retinal degeneration	(257)
Macular degeneration and mild mental retardation; autosomal recessive	(525,540–543)
Spastic paraplegia, short stature, seizures, retinal degeneration, ichthyosiform skin changes; autosomal recessive	(544,545)
<b>Spastic paraplegia and deafness</b>	
SPG29	
Spastic paraplegia, bilateral sensorineural deafness, and intellectual retardation associated with a progressive nephropathy; autosomal dominant	(546)
Spastic paraparesis with short stature, hypogonadism, lens opacities, and deafness	(547)
<b>Spastic paraplegia and skeletal abnormalities</b>	
SPG25	
Skeletal anomalies of the hands and feet (brachydactyly, cone-shaped epiphyses), and dysarthria	(548)
Spastic paraparesis, macrocephaly, distinct craniofacial appearance; autosomal recessive	(549)
<b>Spastic paraplegia and extrapyramidal movement disorder</b>	
HSP types SPG21, 35	
Rhythmic myoclonus of palate, pharynx, larynx, and face; truncal ataxia; probably autosomal dominant	(550)
Spastic paraparesis and extrapyramidal movement disorder; probably autosomal dominant	(525), Dick and Stevenson (1953)
Spastic paraplegia onset second-third decade: basal ganglion manifestations such as dysarthria, and athetosis <sup>a</sup> ; autosomal recessive	(525)
Spastic paraplegia (nonprogressive, infantile onset), distal muscle wasting, mental retardation, short stature; probably autosomal recessive	(530)
<b>Spastic paraplegia and epilepsy</b>	
HSP types SPG35, SPG47	
Spastic paraplegia with epilepsy	(72)
Spastic paraplegia, short stature, seizures, retinal degeneration, ichthyosiform skin changes (Sjogren–Larsson syndrome); autosomal recessive	(544,545)
<b>Spastic paraplegia and dysarthria</b>	
HSP types SPG7, 15, 22, 24, 27, 35, 43, 44,	
Spastic paraplegia and ataxia	See Table 119-1 and text for references
HSP types SPG7, 21, 22, 27, 30, 32, 46	
Spastic paraplegia (early onset) with ataxia, dysarthria, nystagmus, mitral valve prolapse, muscular atrophy; autosomal recessive	(525)
Spastic paraplegia with thin corpus callosum, dementia, ataxia, peripheral neuropathy; autosomal recessive	(551)
<b>Spastic paraplegia and hematologic abnormality</b>	
Spastic paraplegia and May–Hegglin anomaly: cytoplasmic inclusions in leukocytes, giant platelets, and thrombocytopenia; autosomal dominant	(552)
Spastic paraparesis and Evan’s syndrome (Coombs-positive hemolytic anemia and immune thrombocytopenia without a known underlying etiology); probably autosomal recessive	(553)
<b>Spastic paraplegia and MRI brain abnormalities</b>	
HSP types SPG1, 2, 5, 7 (variably abnormal), 11, 15, 18, 21, 32, 35, 44, 46, 47	
<b>Spastic paraplegia and skin abnormalities</b>	
SPG23	
Short stature: seizures, retinal degeneration, ichthyosiform skin changes (Sjogren–Larsson syndrome); autosomal recessive	(544,545)
SPG23 HSP: Childhood-onset spastic paraplegia associated with skin pigment abnormality; autosomal recessive	(263)
Early onset of paraparesis (first decade), peripheral neuropathy, depigmented areas of skin and hair; probably autosomal recessive	(527), Abdallat et al. (1867)
Spastic paraparesis with skin manifestations: vitiligo, hyperpigmentation of exposed areas, multiple lentigines, premature graying of hair, café-au-lait spots; probably autosomal recessive	(554)
Spastic paraplegia, neuropathy, poikiloderma; autosomal dominant	(523)
<b>Spastic paraplegia and endocrine disturbance</b>	
Spastic paraplegia and Kallman syndrome (hypogonadotrophic hypogonadism and anosmia)	(555)

<sup>a</sup>Note that the “complicating feature” may be frequently or infrequently associated with a specific genetic type of HSP.

additional neurologic impairments do not sometimes occur in forms of “uncomplicated” HSP; and (3) assuming (and so counseling subjects and families) that all subjects with a “typically complicated” type of HSP will experience the “complicating” feature (such as mental retardation, epilepsy, or dementia).

**119.1.5.2 Practical Syndrome Recognition: Six HSP Syndromes.** Forms of HSP for which genetic loci have been identified are listed in [Table 119-1](#). On a practical, clinical basis, it is useful to approach the numerous clinical and genetic types of HSP by recognizing six HSP syndromes: (1) uncomplicated HSP; (2) spastic paraplegia associated with peripheral motor neuropathy and/or distal wasting; (3) spastic paraplegia associated with cognitive impairment; (4) spastic paraplegia associated with ataxia; (5) spastic paraplegia associated with neuroimaging abnormality; and (6) spastic paraplegia associated with additional neurologic and systemic abnormalities.

### 119.1.6 Clinical Features of Uncomplicated HSP

Subjects with uncomplicated HSP experience insidiously progressive weakness and increased muscle tone in their legs. These symptoms may begin at any age from early childhood, for example [\(80\)](#), until late adulthood. Gait becomes progressively impaired over many years and subjects often require canes, walkers, or wheelchairs. Urinary urgency and lower extremity paresthesia often occur. In uncomplicated HSP, weakness and paresthesia involve the legs only. In subjects with uncomplicated HSP, there is no weakness, increased muscle tone, slowing of movements, or loss of dexterity or coordination in the upper extremities. Dysphagia and dysarthria are similarly absent in uncomplicated HSP (see [\(24,81–83\)](#) for examples of typical clinical features of uncomplicated HSP).

There is an important exception to the generalization that HSP inevitably causes progressive motor impairment. Many subjects with very early-onset HSP experience very little worsening even over several decades. The disorder in these individuals may resemble that of spastic diplegic cerebral palsy. This is particularly common in SPG3A HSP but also has been described in several other types of HSP [\(60,84\)](#).

*Neurologic examination of uncomplicated HSP subjects* demonstrates bilateral lower extremity weakness and increased muscle tone that is maximal in iliopsoas, hamstrings, and tibialis anterior muscles and which is approximately symmetric; bilateral lower extremity hyperreflexia and bilateral extensor plantar responses. Mildly diminished vibration sensation in distal lower extremities is frequently observed in HSP although, as noted by Brugman et al. [\(85\)](#), may also be present in subjects with primary lateral sclerosis (PLS).

Although upper extremity deep tendon reflexes are often brisk (grades two to three on zero to four scale), it is extremely rare for subjects with uncomplicated HSP to

develop weakness, increased muscle tone, or decreased dexterity of upper extremities. Significant upper extremity weakness is more indicative of motor neuron disorders or PLS than uncomplicated HSP. Similarly, dysphagia, dysarthria, and cranial nerve abnormalities are not features of uncomplicated HSP.

It is not uncommon for subjects with uncomplicated HSP to have decreased muscle mass in distal lower extremities (particularly the shins). While this may reflect disuse atrophy, it may also reflect involvement of anterior horn cells or peripheral motor axons. Slight loss of anterior horn cells has been observed at postmortem examination of uncomplicated HSP (discussed below). Nonetheless, other features of motor neuron disease (muscle cramps, fasciculations, and prominent amyotrophy) are not features of uncomplicated HSP.

*Pes cavus* is often but not invariably present in uncomplicated HSP. *Pes cavus* and hammer toes (hallux flexus) may be prominent in older affected subjects, or conversely, may be absent even in severely affected subjects.

Slight terminal dysmetria on finger-to-nose testing may be present in elderly subjects with otherwise uncomplicated HSP. Tedeschi et al. [\(86\)](#) noted abnormal saccadic eye movements in subjects with otherwise uncomplicated HSP. The occurrence of functionally significant cerebellar disturbance, such as wide-based gait, dysarthria, or oculomotor disturbance, co-inherited with spastic paraplegia would be inconsistent with classification as “uncomplicated” HSP and could represent an olivopontocerebellar atrophy, spinocerebellar ataxia (SCA), or a complicated form of HSP (such as SPG7 HSP due to paraplegin gene mutation).

Subclinical cognitive disturbance and dementia have been reported in some subjects with otherwise uncomplicated HSP. Tedeschi et al. [\(86\)](#) observed cognitive disturbance in five of seven uncomplicated HSP patients, and Lizcano-Gil et al. [\(87\)](#) reported two kindreds with late-onset spastic paraparesis and dementia in whom identification of the genetic locus was not performed. Cognitive disturbance and dementia have been described in uncomplicated autosomal dominant HSP kindreds linked to the SPG4 locus as discussed below [\(88–92\)](#). In general, clinical features of dementia in HSP have included both memory impairment and patterns of behavioral disturbance suggestive of frontotemporal dementia [\(93,94\)](#). Frontotemporal dementia [reviewed in [\(95\)](#)] frequently accompanies ALS, a motor neuron disorder whose neuropathology overlaps that of HSP. Nonetheless, it is not known if dementia in some subjects with HSP is an extra-spinal manifestation of HSP; or represents the occurrence of a separate disorder (such as senile dementia of the Alzheimer’s type) co-segregating with HSP in these kindreds.

**119.1.6.1 Atypical Presentations for “Uncomplicated” HSP.** Additional neurologic impairments may occur in genetic types of HSP typically associated with uncomplicated spastic paraplegia. This phenotype

variation may occur within a family in which all affected individuals share the same HSP gene mutation. The full range and frequency of such atypical presentations and whether each is uniquely associated with a specific mutation is not known. Because SPG3A HSP and SPG4 HSP typically manifest as “uncomplicated” HSP syndromes, the occurrence of additional neurologic abnormalities is particularly noteworthy with these forms of HSP.

**119.1.6.1.1 Cognitive Disturbance in SPG4 HSP.** Most often, subjects with SPG4-linked HSP exhibit uncomplicated spastic paraplegia that begins at any age from childhood to senescence (average age of onset 26–35) (21,59,62,89,92,96–98). Nonetheless, subclinical cognitive disturbance, mental retardation, and dementia have been reported in some SPG4 kindreds (88,89,92,99,100). Scheur et al. (101) reported decreased regional (frontotemporal cortex) cerebral blood flow in SPG4 HSP patients whose neuropsychometric impairment was confined to recognition of faces. Ribai et al. (102) reported 13 patients from three SPG4 HSP families who had cognitive impairment. Among these, one had mental retardation, two had isolated psychomotor delay, and ten had social dependence (five of whom required institutional care). The occurrence of cognitive impairment in some of these SPG4 HSP subjects may be related to a modifying gene because their SPG4 mutations (p.Arg459Thr or p.Arg499Cys) had been previously reported in uncomplicated HSP subjects. It is not known whether nonprogressive cognitive impairment and dementia are unique to SPG4 HSP are more commonly associated with SPG4 HSP compared to other types of “typically uncomplicated” HSP.

**119.1.6.1.2 Unusual Manifestations of SPG4 HSP.** Ataxia, ALS, Thin Corpus Callosum, Muscle Atrophy, Peripheral Sensory-Motor Neuropathy, and Congenital Arachnoid Cysts. As noted above, the single most common cause of autosomal dominant HSP, SPG4 HSP due to SPG4/spastin gene mutation is usually associated with an uncomplicated HSP syndrome. Nonetheless, ataxia, cerebellar atrophy, and posterior fossa developmental abnormality have been reported in SPG4 HSP. For example, Nielsen et al. (103) reported a novel SPG4/spastin mutation (GLN490Stop) in subjects with autosomal dominant HSP associated with cerebellar ataxia. Scuderi et al. (104) reported a kindred with SPG4 due to five base pair deletion in exon 9 (1215-1219delTATAA) in which seven of nine affected subjects had large retrocerebellar fluid collection that was accompanied in three subjects by defect of the posterior part of the tentorium and occipital bone modifications. This report included an additional, unrelated subject with *de novo* SPG4 mutation (p.R581X), who had hypoplasia of the cerebellar vermis.

Alber et al. (105) reported dysplasia of the corpus callosum in one subject with autosomal dominant HSP who had SPG4/spastin mutation C1120A. Other spastic paraplegia subjects in this family did not have corpus

callosum dysplasia, however. Orlacchio et al. (106) also reported congenital arachnoid cysts in HSP subjects with SPG4/spastin T614I mutation.

**119.1.6.1.3 SPG4 HSP Associated with Lower Motor Neuron Involvement Including Peripheral Neuropathy and Muscle Atrophy.** Orlacchio et al. (107) reported peripheral sensory-motor neuropathy and cognitive impairment in subjects with SPG4 906delT frameshift mutation. They also reported (50) a kindred with SPG4 mutation (frameshift mutation p.Asp321GlyfsX6) in which affected subjects exhibited muscle wasting in the hands, cognitive impairment, and temporal lobe epilepsy. The authors noted that distal muscle wasting associated with this SPG4 mutation conformed to “Silver Syndrome” (dominantly inherited spastic paraplegia and distal muscle wasting) (39–41). In light of previous description of distal muscle wasting in subjects with SPG17/BSCL2 mutations (41), this finding indicates that Silver syndrome is genetically heterogeneous.

Meyer et al. (71) described an individual with early-onset, slowly progressive ALS who had spastin gene mutation (c.304\_309dupGCCTCG). See below for further description of the relationship between HSP and ALS.

#### **119.1.6.1.4 Unusual Manifestations of SPG3A HSP.**

**119.1.6.1.4.1 Motor-Sensory Axonal Neuropathy, Distal Wasting, Thin Corpus Callosum, Hereditary Sensory Neuropathy.** Motor-sensory axonal neuropathy, ranging from subclinical involvement evident only on electromyography and nerve conduction studies (which is not uncommon) to severe distal wasting (very rare) is recognized increasingly in SPG3A HSP. Ivanova et al. (108) reported that motor-sensory axonal neuropathy was relatively common (17% of affected subjects) in SPG3A HSP and associated with a number of different SPG3A/atlastin mutations (F151S, Q191R, M408 T, G469A, R495 W). Motor sensory neuropathy was particularly severe in one subject [with M408 T SPG3A mutation (109)] who had severe motor impairment, delayed motor milestones, a combination of global hypotonia and hyperreflexia, marked muscle distal atrophy in all limbs, impaired upper extremity dexterity, dysphagia, and dysarthria. Interestingly, a similar phenotype (although less severe) including impairment of fine hand movements, distal atrophy in the upper extremities, and chronic denervation pattern on electromyography was associated with a separate mutation disturbing this same amino acid (M408 V) (110). Axonal neuropathy has also been reported with SPG3A mutations M347T, R495 W, and S398F (111–113).

Recently, Guelly et al. (114) reported that SPG3A/atlastin mutation p.Asn355Lys was associated with the syndrome autosomal dominant hereditary sensory neuropathy type 1 (HSN 1) rather than with the syndrome of HSP. HSN 1 is an autosomal dominant disorder characterized by marked, early sensory loss (which may be

associated with painless injuries, impaired healing, and osteomyelitis that necessitate amputations). Distal motor involvement may occur in advanced cases (114). The report of Guelly et al. (114) significantly expands the phenotypic spectrum that may be associated with SPG3A/atlastin mutations. These phenotypes include childhood-onset, relatively nonprogressive, uncomplicated spastic paraplegia that resembles spastic diplegic cerebral palsy (the most common SPG3A HSP syndrome); adult-onset, progressive uncomplicated spastic paraplegia (115); spastic paraplegia associated with motor-sensory axonal neuropathy (111); and dominantly inherited sensory neuropathy without spastic paraplegia (114).

The finding that mutation in SPG3A can manifest as sensory neuropathy highlights three other associations between spastic paraplegia and sensory neuropathy. First, subclinical sensory neuropathy has been described in otherwise uncomplicated HSP (116,117). Second, sensory neuropathy, which may be severe, is a feature of SPOAN (spastic paraplegia, optic atrophy, neuropathy) syndrome, linked to chromosome 11q23 (118). And finally, mutations in the *Cct5* gene cause “mutilating sensory neuropathy with spastic paraplegia” due to *Cct5* gene mutation (119–122).

Thin corpus callosum and mental retardation are common features of SPG11 HSP due to Spatacsin mutation (see Table 119-1). Orlacchio et al. (8) reported thin corpus callosum in a South African Zulu family with SPG3A mutation (R416C). In addition to SPG3A and SPG11 HSP, thin corpus callosum has also been described in many types of HSP including SPG4, SPG7, SPG15, SPG21, SPG32, and SPG47 (see Table 119-1).

### 119.1.7 Neurophysiology

*Electromyography and nerve conduction studies.* Although results of these studies are quite variable (both between genetic types of HSP and often within individual families), a number of generalizations can be made. Nerve conduction studies in uncomplicated HSP are usually normal (123–125). Schady and Scheard (116) and Schady and Smith (117), however, found subclinical sensory neuropathy in otherwise uncomplicated HSP. Tredici and Minoli (126) observed degenerative changes in the large myelinated fibers, onion bulb formations, and clusters of small myelinated fibers in a sural nerve biopsy in a 16-year-old subject with autosomal dominant HSP, who had borderline slowing of motor and sensory nerve conduction velocities.

There is increasing awareness that peripheral neuropathy (clinically evident or subclinical) is a feature of many types of HSP, including some of those previously considered to be “uncomplicated.” For example, Ivanova et al. (108) reported motor-sensory axonal neuropathy in 17% of SPG3A HSP subjects. At this stage, the presence of clinically symptomatic peripheral neuropathy would warrant classification as a complicated HSP syndrome

(if neuropathy were part of the inherited syndrome and not due to a coexisting disorder such as diabetes). Nonetheless, it should be noted that nerve conduction studies have not been performed in most subjects with uncomplicated HSP from the various genetic types. Therefore, the true incidence of subclinical peripheral sensory and/or motor nerve involvement in otherwise uncomplicated HSP is not known.

*Somatosensory evoked potentials* (SSEPs) from the lower extremities often, but not always, show conduction delay in dorsal column fibers (123,127–130). In contrast, SSEPs from the upper extremities are usually normal.

*Cortical evoked potentials* [reviewed in (131)], are used to measure the sensitivity of cortical motor neurons and the neurotransmission of corticospinal tracts. These studies have shown greatly reduced conduction velocity and amplitude of evoked potential when stimulating corticospinal tracts subserving the legs (129,131–135). Often, there is no cortical evoked potential elicited in muscles innervated by lumbar spinal segments. These findings indicate that there are decreased numbers of corticospinal tract axons reaching the lumbar spinal cord and that the remaining axons have reduced conduction velocity.

In general, cortical evoked potentials of the arms are usually normal or show only mildly reduced conduction velocity (136). This generalization may not apply to all types of HSP. Recently, for example, Manganelli et al. (137) reported abnormal cortical evoked potentials in both upper and lower extremities (as well as somatosensory, visual, and brainstem evoked potentials) in subjects with SPG5 HSP.

Jorgensen et al. (138) compared motor-evoked potentials in 29 subjects with multiple sclerosis and nine subjects with SPG4 HSP. Using various stimulus intensities, there was no difference in recruitment of motor-evoked potentials between multiple sclerosis and HSP subjects, indicating that this method could not be used to distinguish between these disorders.

Several investigators have reported the peroneal H reflex to be a marker of upper motor neuron involvement in HSP (81,125,134).

Following transcranial magnetic stimulation-induced muscle contraction, there is a period in which voluntary muscle contraction is suppressed. This period, evident by the absence of EMG activity, is referred to as the cortical silent period (CSP) (139) and considered to reflect inhibitory cortical mechanisms (see (139) for methods and discussion of CSP). Sartucci et al. (134) studied 12 subjects with SPG4 HSP and observed that following transcranial magnetic stimulation, the CSP was significantly reduced when measured in the legs and that this correlated with clinical assessments of spasticity. CSP measurements from the hands were normal. Sartucci et al. (134) concluded that shortened CSP reflected impairment of supraspinal or intracortical inhibitory pathways, together with increased segmental motor neuron excitability, and that CSP may be a useful physiologic marker of spasticity.

**119.1.7.1 Central Motor Reorganization in HSP.** As stated by Konrad (140), “plasticity as an intrinsic property of the central nervous system can also be expected in degenerative motor neuron diseases.” Functional reorganization of cortical and subcortical motor networks has been demonstrated in ALS (141,142), and recently in HSP. Using positron emission tomography to study 13 subjects with SPG4 HSP, Scheuer et al. (143) demonstrated that increased activation of cerebral blood flow (in bilateral primary motor cortices, supplementary motor areas, and the right premotor cortex compared to controls) only occur during movement of affected ankles, but not during movements of the unaffected shoulders. These results suggest that upper motor neuron degeneration in SPG4 HSP (and presumably other types of HSP) is sufficient to induce cortical reorganization. Whether the process of cortical reorganization itself is influenced by HSP gene mutation and the extent to which cortical reorganization contributes to clinical manifestations of HSP (such as influencing the apparent rate of progression or response to therapy) are unknown.

### 119.1.8 Neuroimaging

Brain and spinal cord MRI scan are important in the clinical evaluation of subjects suspected as having HSP as part of the exclusion of alternative or coexisting disorders (see Table 119-3).

**119.1.8.1 Spinal Cord MRI.** The primary neuropathology of uncomplicated HSP is axonal degeneration that is maximal in the ends of the lateral corticospinal tracts in the thoracic spinal cord; and the ends of *fasciculus gracilis* fibers in the cervical-medullary region. This axonal degeneration may be severe enough to affect the cross-sectional area of the spinal cord on magnetic resonance imaging (MRI). Spinal cord MRI in HSP subjects has been normal (144); or has shown mild to marked atrophy of cervical and thoracic segments (31,145–148). For example, Hedera et al. (146) reported significantly reduced cervical (C2) and thoracic (T9) spinal cord cross-sectional areas in subjects with four different types of autosomal dominant HSP (SPG3A, SPG4, SPG6, and SPG8). Spinal cord atrophy was more prominent in patients with SPG6 and SPG8 than in subjects with SPG3 and SPG4.

Vassilopoulos et al. (149) reported decreased sagittal and transverse diameter of cervical and thoracic spinal canal in HSP subjects compared to normal control subjects. They concluded that this indicated that the patterns of growth of spinal cord (which may be atrophic in HSP) and the spinal canal are parallel.

**119.1.8.2 Brain MRI.** Although conventional brain MRI is usually normal in uncomplicated HSP, detailed measurements (using brain parenchymal fractions calculated from three-dimension MRI data) have shown reduced brain volumes in both uncomplicated and complicated

**TABLE 119-3 Differential Diagnosis of HSP**

Category	Disorder	Clinical Features that Differentiate from HSP	Diagnostic Evaluation
Structural spinal cord abnormality	Arnold–Chiari malformations	Ataxia	Magnetic resonance imaging (MRI) of posterior fossa
	Cervical or lumbar spondylosis	Involvement of upper extremities; radiculopathy	Spine X-rays and MRI
	Tethered cord syndrome		MRI of conus medullaris
	Neoplasm involving spinal cord	Pain, loss of sensation, asymmetric involvement	MRI of spinal cord
	Spinal cord arteriovenous malformation	Saltatory progression; spinal sensory level	MRI, spinal arteriography
	Granuloma (e.g., Tuberculosis) involving vertebrae with spinal	Back pain, subacute course	Spine X-rays and MRI
Degenerative diseases	Multiple sclerosis	Exacerbations, remissions, ataxia, optic neuritis, Lhermitte’s sign	MRI, cerebrospinal fluid examination, visual evoked potentials
	Amyotrophic lateral sclerosis	Fasciculations, amyotrophy	Electromyography and nerve conduction testing
	Primary lateral sclerosis	PLS is typically sporadic. HSP may have dorsal column disturbance which is not a feature of PLS.	Family history, dorsal column impairment (evident clinically or with somatosensory evoked potentials)
	SCA including Machado–Joseph disease	Ataxia, dysarthria	Prominent ataxia; Machado–Joseph disease also has extrapyramidal involvement
	Friedreich’s ataxia	Peripheral neuropathy	FRDA gene testing

*Continued*

TABLE 119-3 Differential Diagnosis of HSP—cont'd

Category	Disorder	Clinical Features that Differentiate from HSP	Diagnostic Evaluation
Metabolic disorders <sup>a</sup>	Adrenoleukodystrophy (ALD), adrenomyeloneuropathy (AMN)	ALD and AMN are X-linked. In childhood-onset a/d progressive cognitive impairment and peripheral neuropathy accompany corticospinal tract signs. In adolescent/adult-onset AMN, cognition is normal peripheral neuropathy is variable.	Serum very long chain fatty acid analysis
	Metachromatic leukodystrophy (MLD)	MLD (autosomal recessive) in children is typically associated with psychomotor regression and peripheral neuropathy.	MRI (brain), arylsulfatase
	Krabbe (globoid cell) leukodystrophy	Krabbe disease is an autosomal recessive disorder. Peripheral neuropathy, a feature of childhood-onset Krabbe disease, may be absent in adolescent/adult-onset Krabbe disease.	MRI (brain), galactocerebrosidase
	Subacute combined degeneration	Peripheral neuropathy, marked dorsal column involvement	Serum vitamin B12 concentration
	Mitochondrial encephalomyopathy	Short stature, retinitis pigmentosa, and multiple stroke-like episodes may help distinguish this diverse group of disorders from HSP	MRI (brain), serum lactate and pyruvate
	Abetalipoproteinemia (Bassen–Kornzweig disease)	Peripheral neuropathy	Lipoprotein electrophoresis
	Methylenetetrahydrofolate reductase deficiency	Psychiatric disturbance, spastic paraplegia, neuropathy; thromboemboli	Hyperhomocysteinemia, hypomethioninemia, low folic acid
	Cobalamin C defect	Psychiatric disturbance, peripheral neuropathy, dorsal column impairment, retinitis pigmentosa	Hyperhomocysteinemia, hyomethioninemia, methylmalonic aciduria
	Arginase deficiency and	Episodic nausea, vomiting, headache, confusion triggered by high protein intake	Hyperargininemia, (variable hyperammonemia
	Hyperornithinemia-hyperammonemia-hypercitrullinemia)	Episodic nausea, vomiting, triggered by high protein intake; ataxia, mental retardation	Hyperammonemia
	Biotinidase deficiency	Optic atrophy, deafness, neuropathy, dermatitis, alopecia	Serum biotinidase activity
	Phenylketonuria	Extrapyramidal disturbance, dementia, mental retardation	Serum phenylalanine
	Nonketotic hyperglycinemia	Mental retardation, ataxia, neuropathy, optic atrophy	Serum glycine
	Central folate deficiency	Extrapyramidal disturbance, deafness, ataxia, atrophy	Low 5-methyltetrahydrofolate concentration in CSF
	Cerebrotendinous xanthomatosis	Juvenile cataracts, tendon xanthoma, peripheral neuropathy, leukodystrophy	Serum cholestanol
	Vitamin E deficiency	Peripheral neuropathy	Serum vitamin E concentration
Infectious diseases	Tertiary syphilis (hypertrophic pachymeningitis)		VDRL, FTA
	Tropical spastic paraparesis	Subacute course	HTLV-I antibodies
	Acquired immunodeficiency syndrome (AIDS)	Subacute course	HIV antibodies
Miscellaneous	DOPA-responsive dystonia	Diurnal fluctuation; response to low-dose levodopa-carbidopa	Therapeutic trial of low-dose levodopa-carbidopa

<sup>a</sup>See Reference (219).  
Modified from (59).

HSP subjects (150). Brain MRI in HSP subjects may also disclose syndrome-specific abnormalities including hydrocephalus [typical of X-linked SPG1 HSP due to L1CAM mutation (151,152)], thin corpus callosum [discussed below, common in SPG11 but also reported in SPG3A, SPG4, SPG7, SPG15, SPG21, SPG32, SPG47, and the syndrome “HSP with thin corpus callosum and epilepsy” (8,153,154)], and cerebellar atrophy (which is frequent in SPG7 HSP (155) and uncommon in SPG4 HSP (103)).

*Diffusion Tensor Imaging (DTI)* in the brain of HSP subjects has shown evidence of corticospinal tract degeneration. Duning et al. (100) performed DTI in six uncomplicated SPG4 HSP subjects and observed widespread white matter disturbance primarily affecting corticospinal tracts. Interestingly, these white matter abnormalities were present in subtly affected subjects (with isolated hyperreflexia) who had pathogenic SPG4 mutations. Similarly, Unrath (156) performed DTI in 24 HSP subjects (six with SPG4/spastin mutations) and reported predominant deterioration of corticospinal tracts in addition to widespread white matter abnormalities.

DTI has shown more widespread involvement in complicated HSP due to SPG11/spatacsin mutation. Chen et al. (157) performed DTI in two SPG11 HSP subjects with thin corpus callosum and observed increased mean diffusivity and fractional anisotropy to be much more widespread (brainstem, internal capsule, cingulum and subcortical white matter including superior longitudinal fascicle and inferior longitudinal fascicle) than previously recognized (corpus callosum, cerebellum, and thalamus) or evident on conventional MRI.

**119.1.8.3 Magnetic Resonance Spectroscopy.** Erichsen et al. (158) reported abnormal brain magnetic resonance spectroscopy in a study of eight subjects with SPG4 HSP and reported abnormal brain. They observed that the choline-to-creatine ratio was significantly reduced in motor cortex of HSP subjects (compared to control subjects); and that reduced choline-to-creatine ratio was associated with reduced verbal learning and memory in the SPG4 HSP subjects.

Dreha-Kulaczewski et al. performed serial magnetic resonance spectroscopy and DTI in a 25-year-old subject with adolescent-onset spastic paraplegia, dementia, and dysarthria. Genetic type of HSP was not determined (159). Magnetic resonance spectroscopy of white matter revealed metabolic abnormalities (reduced concentrations of N-acetylaspartate and N-acetylaspartyl-glutamate, creatine and phosphocreatine, and choline-containing compounds and elevated levels of myo-inositol) that showed progression over 5 years. DTI showed increased diffusivity and reduced fractional anisotropy in periventricular white matter. These findings were interpreted as indicating axonal degeneration and astrocyte proliferation in white matter.

**119.1.8.4 Variable Degree of White Matter Disturbance Occurs in Some Types of HSP.** It is noteworthy that spinal cord and brain MRI in uncomplicated HSP usually do not show evidence of demyelination (despite neuropathologic evidence of myelin loss commensurate with axonal degeneration in the spinal cord). On the other hand, white matter abnormalities have been observed in many forms of complicated HSP (e.g., due SPG5/CYPB7, SPG7/Paraplegin, SPG21/Masparidin, and SPG35/FA2H gene mutations, see Table 119-1) (78,155,160–163).

In humans, heterozygous mutation of the spastin gene causes distal axon degeneration in SPG4 HSP, the single most common form of dominantly inherited HSP. Mild demyelination of corticospinal tracts is also noted and is considered commensurate with, and secondary to, axon degeneration. In contrast, in congenital bovine dysmyelination, homozygous mutation of the bovine spastin gene causes severe dysmyelination (164). It is not clear why homozygous spastin mutation in cattle causes predominant dysmyelination while heterozygous spastin mutation in humans causes primarily axonal degeneration. Our SPG4/spastin mutant mice did not show extensive demyelination in homozygous mutant animals (J. K. Fink, et al. unpublished studies). If this can be extrapolated to cattle, it is therefore unlikely that dysmyelination is due to homozygosity of the spastin mutation alone.

Although white matter abnormalities may be evident in brain MRI in some forms of HSP, evidence of significant, generalized demyelination should prompt further diagnostic evaluation for leukodystrophies unrelated to HSP. For example, extensive white matter disturbance in subjects with X-linked spastic paraplegia would raise the possibility of adrenomyeloneuropathy or proteolipid protein (PLP) gene mutation (causes allelic disorders X-linked, SPG2 HSP, and the dysmyelinating disorder, Pelizaeus–Merzbacher, discussed below).

As noted above, the primary pathology of uncomplicated (and many forms of complicated) HSP is axon degeneration (maximal at the distal ends of corticospinal tracts and dorsal column fibers). Nonetheless, for most types of HSP, it is not known whether axon degeneration is “cell autonomous” (due to intrinsic disturbances only in neurons) or “non-cell autonomous” (axon degeneration depends in part on interaction with nonneuronal cells). Some HSP genes are primarily expressed in oligodendroglia and not neurons (e.g., PLP and GJA12/Connexin 47, mutations in which cause SPG2 and SPG42, respectively). Proteins encoded by these genes are important factors in myelin formation. These examples indicate that axon degeneration in these types of HSP is non-cell autonomous; and furthermore, underscore the concept that primary disturbance of myelin can result in axon abnormalities.

*Thin corpus callosum* (particularly its anterior portion) initially was identified as a very frequent (but not constant) feature of SPG11 HSP (e.g., (159,165–169)).

Subsequently, thin corpus callosum has been reported in many forms of HSP, including “typically uncomplicated” types (SPG3A and SPG4) (8,105); and “typically complicated” types of HSP (SPG7, SPG15, SPG21, SPG32, and the syndrome “HSP with thin corpus callosum and epilepsy” (153,154)). Whereas thin corpus callosum in SPG11 HSP is usually associated with cognitive impairment (studied in detail in two subjects by Siri et al. (170)), thin corpus callosum in other types of HSP is not always associated with cognitive impairment. For example, Alber et al. (105) reported thin corpus callosum in one of two affected subjects with SPG4 HSP (due to Spastin mutation C1120A) that was not associated with cognitive impairment.

Rather than being simply a coexisting feature accompanying some forms of HSP, corpus callosal abnormalities may contribute to spastic gait. As noted by van Swigchem et al. (171), damage to the corpus callosum is frequent in spastic diplegic cerebral palsy. These authors found that transcallosal inhibition (suppression of voluntary electromyographic activity in ipsilateral muscles after focal transcranial magnetic stimulation) in the upper extremities was abnormal in cerebral palsy patients with upper extremity involvement, but was normal in subjects with HSP who did not have upper extremity involvement or thin corpus callosum. It is tempting to speculate that transcallosal inhibition of the lower extremities contributes to spasticity in subjects with HSP who have thin corpus callosum.

### 119.1.9 Neuropathology

Schwarz (172), Schwarz and Liu (173), Deluca et al. (174), and White et al. (175) reported postmortem findings of uncomplicated HSP subjects as showing the following: (1) demyelination and destruction of axis cylinders in lateral corticospinal tracts, primarily in the thoracic spinal cord with less severe involvement in the cervical spinal cord; (2) less severe demyelination of ventral corticospinal tracts (in four of seven subjects); (3) demyelination of spinocerebellar tracts; (4) demyelination of fasciculus gracilis, consistently more severe in the cervical spinal cord; (5) diminished number of neurons in Clarke’s columns (in two of seven subjects); (6) decreased number of anterior horn cells (in one of seven subjects); (7) minor changes in cerebellum, basal ganglia, and rubrospinal tract (in one of seven subjects); (8) changes in the internal capsule, cerebral peduncles, pons or medulla (in one of seven subjects); atrophy or decreased numbers of Betz cells (in three of seven subjects). Behan and Maia (176), Harding (58), Sack et al. (177), and Buge et al. (178) confirmed the primary neuropathology of uncomplicated HSP as demonstrating primary axonal degeneration that was maximal in distal aspects of the corticospinal tracts in the thoracic spinal cord, and to a lesser extent, the distal ends of dorsal column fibers (especially fasciculus gracilis fibers) in the cervicomedullary region. Mild loss

of anterior horn cells may be observed. Demyelination, if present, is generally consistent with the degree of axonal degeneration (although, as discussed above, many forms of complicated HSP have significant white matter abnormalities).

There are very few reports of postmortem studies in which the genetic type of HSP is known. Wharton et al. (179) reported postmortem examination in three SPG4/spastin mutation HSP subjects. Typical of previous neuropathologic findings, they identified distal degeneration of long tracts in the spinal cord accompanied by a microglial reaction. In addition, they reported cytopathologic findings of anterior horn cells (novel hyaline inclusions), alteration in immunostaining for cytoskeletal proteins (nonphosphorylated neurofilament protein and  $\beta$ -tubulin), and abnormal mitochondrial distribution as well as evidence of tau pathology outside the motor system. In addition to confirming distal degeneration of long axons, these findings highlight involvement (albeit usually subclinical) of anterior horn cells. These findings also indicate that neurodegeneration is widespread in SPG4 HSP, the single most common form of dominantly inherited HSP. Moreover, findings indicative of cytoskeletal protein disturbance may be consistent with spastin’s microtubule severing properties and effect of spastin mutations on axonal transport (180–182).

White et al. (175) reported neuropathologic findings in a subject with HSP due to SPG4/spastin mutation (R424G) who had dementia, decreased facial expressions, and mild tremor. Their findings were consistent with previous descriptions of axonopathy in HSP including corticospinal tract degeneration that was maximal in thoracic and lumbar cord, associated myelin pallor, preservation of corticospinal tracts in cerebral peduncles, and no evidence of loss of anterior horn cells or Betz cells. Regarding dementia, the hippocampus showed loss of neurons with remaining neurons displaying frequent neurofibrillary tangles that were immunoreactive for tau. There was severe neuronal loss and neurofibrillary tangle formation in the entorhinal cortex. Senile plaques were not observed. Ballooned neurons with granulovacuolar degeneration, and stained strongly for tau and  $\alpha$ - $\beta$ -crystallin, were especially prominent in limbic areas. Consistent with the subject’s decreased facial expressions and mild tremor, the substantia nigra showed moderate loss of pigmented dopaminergic neurons and frequent Lewy bodies and pale bodies.

Kuru et al. (183) reported postmortem findings in an individual with HSP and thin corpus callosum. The genetic type of HSP was not determined. In addition to adolescent-onset progressive spastic weakness in both legs, this subject manifested upper extremity involvement (spastic tetraplegia), dementia, neuropathy, and muscle wasting. Autopsy revealed a marked brain atrophy, extremely thin corpus callosum and widespread neurodegeneration involving corticospinal tracts, thalamus, cerebral white matter, and substantia nigra.

Degenerative changes involving anterior horns and dorsal columns were also observed. Significant accumulation of lipofuscin and eosinophilic granules was noted in remaining neurons. The authors commented that the occurrence of severe gliosis in the cerebral white matter and substantia nigra indicated that neurodegeneration likely followed substantially normal neurodevelopment, and therefore the primary process was neurodegenerative rather than developmental abnormality.

It is difficult to make generalizations from individual postmortem descriptions of isolated subjects with spastic paraplegia syndromes, particularly when the genetic mutation is not known. As noted above, progressive spastic paraplegia may be a feature of numerous disorders, not all of which are properly classified as HSP. Indeed, given the fact that uncomplicated HSP usually does not shorten the life span, there may be ascertainment bias toward greater number of postmortem studies in subjects with unusual, complicated, and severe spastic paraplegia syndromes. (See, e.g., the description by Nomura et al. (184) of postmortem findings in an individual with a likely autosomal recessive spastic paraplegia syndrome that was complicated by upper extremity involvement, dysarthria, and dementia, becoming bedridden at age 40 and leading to death at age 50 from aspiration pneumonia.)

### 119.1.10 Diagnostic Criteria of Uncomplicated HSP

HSP is diagnosed *clinically* by the following criteria (59): (1) *characteristic clinical symptoms* of bilaterally symmetric, lower extremity spastic weakness that progresses insidiously (when symptoms begin after childhood) or essentially nonprogressive (when symptoms begin in early childhood); (2) *neurologic examination* demonstrates approximately symmetric deficits involving corticospinal tracts subserving the bilateral lower extremities [lower extremity spastic weakness, hyperreflexia, and typically extensor plantar responses (occasionally, plantar responses are flexor in obviously affected subjects) (36)], often accompanied by mildly impaired vibration sensation in the distal lower extremities, hypertonic urinary bladder, and pes cavus; (3) *family history* consistent with inheritance of an autosomal dominant, autosomal recessive or X-linked disorder; (4) *and most importantly, exclusion of alternate and coexisting diagnoses* (Table 119-3). The role of HSP gene analysis in confirming the clinical diagnosis of HSP is discussed below.

*Laboratory testing for HSP gene mutations* is increasingly available. Mutations in 22 genes have been discovered, which are associated with various HSP syndromes. In the United States, commercial analysis is available for X-linked, SPG2/PLP gene (tested at several laboratories, including A.I. duPont Nemours Hospital, Wilmington, Delaware), SPG3A/Atlastin, SPG4/spastin, SPG6/NIPA1, SPG7/Paraplegin, SPG8/Strumpellin,

SPG11/Spatacsin, SPG17/BSCL2, and SPG31/REEP1 available through Athena Diagnostics (Boston, MA). Together, this gene analysis will confirm the diagnosis in ~75% of autosomal dominant HSP. In addition, depending on the extent of genetic testing, ~10–20% of subjects with no family history of HSP (“apparently sporadic spastic paraplegia,” discussed later in the chapter) can be shown to have a potentially pathogenic mutation in an HSP gene for which testing is clinically available (185,186).

HSP gene testing is used most reliably to confirm the clinical diagnosis of HSP. When an HSP gene mutation is identified in an affected subject with clinically definite HSP, this information can be applied to prenatal genetic testing (187–189).

**119.1.10.1 Limits to HSP Gene Analysis and Interpreting the Relevance of HSP Gene Variations of “Unknown Significance”.** HSP gene testing must be interpreted in light of the clinical syndrome. It is very difficult to know the significance (including implications for genetic counseling) of a novel HSP gene variation in a subject who does not meet clinical diagnostic criteria for HSP.

In the case of SPG4/spastin, more than 300 mutations have been reported, the majority of which are “private,” being uniquely present in the family in which they are discovered. In this situation, it is common for an affected subject to have a novel SPG4/spastin mutation that is of uncertain significance. Often, clinicians must decide whether the mutation is likely to be pathogenic and the proper explanation for the patient’s symptoms. Although molecular abnormalities (such as microtubule severing function), in vitro models, and in vivo models associated with SPG4/spastin mutation are being studied, these have not yet been translated into validated biochemical or functional assays that can be used to evaluate the significance of novel SPG4/spastin mutations (or mutations in other HSP genes). Whether the subject actually has HSP depends more on the constellation of clinical features, family history, and exclusion of alternate disorders than on the results of HSP gene analysis alone. Even with the emerging availability of laboratory-based testing to confirm the diagnosis of HSP, it is still important that subjects with progressive spastic paraparesis undergo evaluation, including neuroimaging as indicated, to exclude alternative or coexistent disorders.

There are important limits to HSP gene testing. Presently, gene testing is available commercially for only a subset ( $N = 9$ ) of identified HSP genes ( $N = 22$ ), which in turn represent less than half of the known genetic types of HSP ( $N = 50$ ). Gene testing for other discovered HSP genes is available only on a research basis. For genes whose analysis is commercially available, only the coding sequences and intron-exon splice junctions are examined. In the case of SPG4/spastin, exon deletion is also assessed (responsible for ~10% of SPG4 HSP). For SPG2/PLP, gene copy number is also evaluated. Sequence

abnormalities in gene promoter and other gene regulatory elements are not assessed. Therefore, while identification of an HSP gene mutation of known or likely pathogenic significance can confirm the clinical diagnosis of HSP, the absence of a detectable mutation among currently available HSP genes does not exclude the diagnosis.

### 119.1.11 Differential Diagnosis

It is important to consider HSP a diagnosis of exclusion and to use appropriate laboratory and neuroimaging studies to rigorously exclude other disorders. Consideration of these alternative disorders (see Table 119-3 and (190)) is most relevant when examining patients with atypical features and those with no family history of a similar disorder. Clearly, the presence of neurologic or systemic abnormalities, in addition to spastic paraplegia, does not exclude the diagnosis of HSP but rather may indicate a form of “complicated” HSP. Documenting associated deficits (such as ataxia, retinitis pigmentosa, peripheral neuropathy, amyotrophy, and extrapyramidal signs) is the basis for classifying HSP patients as uncomplicated or complicated and helps distinguish uncomplicated HSP from other neurologic disorders.

The differential diagnosis of *uncomplicated HSP* includes *structural abnormalities* involving the brain or spinal cord, such as tethered cord syndrome and spinal cord compression (191); *other motor neuron disorders* such as slowly progressive ALS (which may present at an early age with insidiously progressive lower extremity weakness, hyperreflexia, and distal amyotrophy) (192–195); PLS (discussed below); distal hereditary motor neuropathy (196); *leukodystrophies* such as steadily progressive multiple sclerosis (197) and Pelizaeus–Merzbacher disease (PMD) (X-linked, allelic with SPG2 HSP), Pelizaeus–Merzbacher-like disease (PMLD) (allelic with SPG44 HSP), and those due to metabolic abnormalities such as B12 deficiency, Krabbe disease (autosomal recessive), metachromatic leukodystrophy (autosomal recessive), and adrenomyeloneuropathy (which, though X-linked, has mimicked autosomal dominant HSP) (198–201); SCAs, such as Machado–Joseph disease SCA 3, which may include spasticity (202–205), or other SCAs including SCA type 17 (206) and SCA 28 (207); Friedreich’s ataxia [which may present with spasticity instead of hyporeflexia, see, e.g., (208)]; olivopontocerebellar atrophy (209), autosomal recessive spastic ataxia of Charlevoix–Saguenay (210), and spastic ataxia due to mitochondrial mRNA maturation (211). Regarding *mitochondrial disturbance*, it is notable that abnormalities involving mitochondrial proteins underlie at least four forms of HSP: SPG7 (paraplegin gene), SPG13 (heat shock protein 27 gene), SPG31 (REEP1 gene), and the mitochondrial ATP6 gene (212). These examples of autosomal recessive (SPG7/Paraplegin, SPG13/heat shock protein 27), autosomal dominant (SPG31/REEP1), and maternal (mitochondrial ATP6 gene) inheritance of

mitochondria-related HSP highlight the importance of considering mitochondrial disorders whose wide variety of clinical presentations may include spastic paraplegia (213,214).

The differential diagnosis of progressive spastic paraplegia includes viral infection with human immunodeficiency virus (HIV/AIDS) as well as tropical spastic paraplegia [also known as human T-cell leukemia virus 1 (HTLV1)-associated myelopathy] (203). Familial clusters of tropical spastic paraplegia have been reported (215–218).

Although pediatricians, geneticists, and neurologists are well aware of the numerous metabolic disorders associated with lower extremity spastic weakness in childhood, there is much less awareness that many of these disorders also may begin later in adolescence and adulthood and manifest as either “uncomplicated” progressive spastic paraplegia or “complicated” spastic paraplegia syndromes. Sedel et al. (219) reviewed metabolic disorders in which adult-onset spastic paraparesis is reported to be a presenting sign or an important feature. It is very important to note that treatment approaches exist for many of these disorders (reviewed in Sedel et al. (219), see Table 119-3).

In addition to adrenomyeloneuropathy, Krabbe disease, and metachromatic leukodystrophy, discussed above, these disorders include homocysteine remethylation defects due to methylene tetrahydrofolate reductase deficiency and cobalamin C disease, urea cycle defects (in particular, arginase deficiency and hyperornithinemia–hyperammonemia–homocitrullinuria syndrome), biotinidase deficiency, phenylketonuria, nonketotic hyperglycinemia, cerebral folate deficiency, homocarnosinosis, cerebrotendinous xanthomatosis (220), Sjögren–Larsson syndrome [caused by deficiency of fatty aldehyde dehydrogenase (FALDH)], polyglucosan body disease, and nucleoside phosphorylase deficiency (221). For review of these disorders including a summary of their clinical presentation, diagnostic testing, and treatment, see Sedel et al. (219).

Insofar as some forms of HSP are associated with dementia (discussed above), the differential diagnosis in appropriate individuals may extend to frontotemporal dementia (95) as well as dementia related to presenilin 1 gene mutation whose presentation may include lower extremity spasticity (222).

Dopa-responsive dystonia should be considered in all subjects, particularly children with progressive gait disturbance. We often recommend a 2-week trial of levodopa-carbidopa, increasing to 25/100 B.I.D. Although rare, dopa-responsive dystonia is treatable with low-dose levodopa-carbidopa (223,224).

Note that the differential diagnosis of HSP includes familial clustering of nongenetic disorders (tropical spastic paraparesis) (215–218), disorders for which specific treatments are available (e.g., B12 deficiency, DOPA-responsive dystonia, cervical spondylosis), and those

whose prognosis differs significantly from HSP (e.g., familial ALS and PLS).

### 119.1.12 Genetic Types of HSP: Autosomal Dominant, Autosomal Recessive, X-linked, and Maternal Inheritance

Each of these types of HSP is genetically heterogeneous: mutations in separate genes cause disorders that share the feature of lower extremity spastic weakness. Some forms of HSP are indistinguishable clinically while others are recognized by syndrome-specific constellations of neurologic (and sometimes systemic) features. Genetic loci for HSP are designated “spastic gait” (SPG) loci 1 through 48, in order of their discovery. In addition, there are several forms of HSP that do not have SPG loci designations (Table 119-1).

**119.1.12.1 Autosomal Dominant HSP Shows Extreme Genetic Heterogeneity.** The first locus for autosomal dominant HSP was identified by Hazan et al. (15) on chromosome 14 and designated SPG3 (X-linked HSP loci SPG1 and SPG2 had previously been described). Hazan et al. (15) and others (225) demonstrated that autosomal dominant HSP was genetically heterogeneous by identifying other autosomal dominant HSP kindreds for which SPG3 locus was excluded. To date, 19 genetic loci for autosomal dominant HSP have been identified (Table 119-1). The existence of one additional locus (SPG40) was suggested by exclusion of the then known HSP loci (51).

SPG4 HSP, due to mutations in the *SPG4*/spastin gene (discussed below), is the single most common type of dominantly inherited HSP, representing ~40% of autosomal dominant uncomplicated HSP kindreds (61,82). Next in frequency is SPG3A (due to mutations in the *SPG3A*/atlastin gene) and SPG6 (due to mutations in the *SPG6*/NIPA1 gene), which represent ~15% and ~5% of dominantly inherited HSP, respectively. Other types of dominantly inherited HSP are much less common, each having been reported in only one family or at most in several families.

**119.1.12.2 Genotype-Phenotype Correlation in Autosomal Dominant HSP.** The phenotype spectrum and therefore genotype–phenotype correlations are poorly understood for most types of HSP. This is largely because clinical descriptions for many genetic types of HSP are based on only one or several families, and detailed, longitudinal analyses to document the natural history are rare. With this proviso, a number of generalizations can be made.

“Complicated” forms of HSP (summarized in Table 119-1) are distinguished by the presence in the *majority of subjects (but perhaps not all)* of clinical features in addition to lower extremity spastic weakness. Clearly, some subjects with some types of HSP considered to be “complicated” (e.g., SPG10 due to KIF5A mutation) may have “uncomplicated” HSP syndromes (34). Conversely,

additional neurologic impairments (and therefore “complicated HSP syndromes”) may occur in some subjects with types of HSP generally considered to be “uncomplicated”. For example, although SPG3A and SPG4 HSP are usually “uncomplicated”, SPG3A HSP may be associated with peripheral axonal neuropathy and muscle atrophy; and SPG4 HSP may be associated with dementia, peripheral axonal neuropathy, thin corpus callosum, and muscle atrophy. In general, it is not possible to attribute these “variant” presentations to specific gene mutations.

For subjects manifesting the syndrome of autosomal dominant, uncomplicated progressive spastic paraplegia, it is generally not possible to distinguish reliably the genetic type of HSP using clinical parameters alone (59,62,82,96,226,227). This is due, in part, to the narrow diagnostic criteria of uncomplicated HSP in which the inherited syndrome is limited to insidiously progressive, symmetric, spastic weakness of the lower extremities, frequently accompanied by urinary bladder disturbance and mild impairment of vibration sensation in distal lower extremities.

There is variability, however, in the age at which symptoms first appear and the extent of functional disability. These features are variable both within a given kindred, between kindreds linked to the same locus, and between different genetic types of HSP. In general, symptoms begin earlier (less than age 11 years, on average) in SPG3A, SPG10, and SPG12 than for SPG4, SPG6, SPG8, and SPG13 (in which symptoms begin after age 20, on average) (62). Although various types of dominantly inherited HSP differ in the *average* age-of-symptom onset, there is considerable overlap in the *range* of ages when symptoms first appear between various types of HSP. This finding limits the ability to predict the HSP locus from the age-of-symptom onset *alone*.

*Autosomal dominant*, “typically complicated” and “variably complicated” HSP includes those syndromes in which spastic paraplegia is *usually or often* associated with additional neurologic abnormalities. These include SPG17 HSP (Silver syndrome, due to *BSCL2*/seipin gene mutation discussed below) in which dominantly inherited spastic paraplegia is associated with distal muscle atrophy (41); SPG9 HSP in which dominantly inherited spastic paraplegia is associated with cataracts, gastroesophageal reflux, and motor neuropathy (33); and SPG29 HSP in which spastic paraplegia associated with hearing impairment and persistent vomiting and hiatal hernia (228).

In some forms of dominantly inherited HSP, the “complicating features” are *variably present*. For example, SPG10 HSP (due to mutations in the *KIF5A* gene discussed below) is a dominantly inherited HSP syndrome in which affected subjects may have either uncomplicated spastic paraplegia; or spastic paraplegia complicated by distal muscle atrophy (229). In addition, although SPG3A HSP (due to *SPG3A*/atlastin gene

mutation) typically is “uncomplicated,” peripheral axonal neuropathy has been reported in ~17% of subjects with (108).

**119.1.12.3 Genetic Anticipation in Autosomal Dominant HSP.** Some autosomal dominant HSP kindreds exhibit progressively younger age-of-symptom onset or increased disease severity in succeeding generations. Although genetic anticipation is not typical of all dominantly inherited types of HSP (59), it has been reported in SPG4 HSP (98,230–233) and observed in SPG3A HSP. Despite these observations, tandem repeat expansions, the molecular mechanism responsible for genetic anticipation in more than two dozen inherited neurologic disorders, have not been identified in HSP with anticipation for which HSP gene mutations have been identified. In contrast, the HSP gene mutations in such families have been point mutations, deletions, and aberrant splicing. For example, we identified an SPG3A HSP family in which the 73-year-old grandfather was neurologically normal, his son had mild spastic gait beginning in his 20s and his grandson had marked spastic gait beginning at age 7 (234,235). Each of these individuals was heterozygous for SPG3A/atlastin mutation V253I.

The absence of trinucleotide (or other) repeat expansion in families with apparent genetic anticipation could be explained by the presence of an expanded repeat in an HSP modifying gene (236); a molecular mechanism for anticipation other than tandem repeat expansions; or ascertainment bias, in which variable age-of-symptom onset in small families is interpreted as an intergenerational trend toward earlier symptom onset.

### 119.1.13 Autosomal Recessive HSP

In Norway, the prevalence of autosomal recessive HSP was determined to be 0.6 per 100,000, being less prevalent than autosomal dominant HSP (5.5 per 100,000) and isolated cases of spastic paraplegia (1.3 per 100,000) (13). Individuals with autosomal recessive HSP (like those with other autosomal recessive disorders) often do not have family history of similarly affected relatives (because parents, children, and, on average, 75% of siblings of individuals with recessive disorders are unaffected). Therefore, we may underrecognize the genetic basis for the disorder in many individuals with “apparently sporadic” spastic paraplegia (ASSP). Indeed, analyses of ASSP subjects consistently identify gene mutations in both autosomal recessive and autosomal dominant types HSP. For example, Brugman et al. (185) reported that 6.7% of subjects (7 of 105) with apparently sporadic upper motor neuron syndromes had potentially pathogenic SPG4/spastin mutations. In addition, 11% (7 of 65) spastic paraplegia subjects had homozygous or compound heterozygous SPG7/paraplegin mutations (185,237).

Hentati et al. (238) studied Tunisian HSP kindreds and identified the first locus for autosomal recessive HSP

(SPG5) on chromosome 8. Subsequently, DeMichele et al. (155), Garner et al. (239), and Martinez-Murillo et al. (240) identified autosomal recessive HSP loci on chromosomes 16 (SPG7) and 15 (SPG9), respectively. Presently, 26 loci for autosomal recessive HSP have been identified. SPG11 is the single most common genetic type of autosomal recessive HSP, initially estimated to be responsible for 50% of autosomal recessive HSP (240). SPG11 HSP often (not always) presents as a “complicated” spastic paraplegia syndrome, typically (though not always) associated with thin corpus callosum and mental retardation (and sometimes associated with distal wasting and retinal pigmentary abnormality, conforming to Kjellin syndrome, discussed below). The proportion of SPG11 among autosomal recessive forms of HSP varies in part on whether subjects were selected on the basis of corpus callosum thinning. For example, Shibasaki et al. (241) showed that 10 of 13 (77%) Japanese families with autosomal recessive HSP, mental retardation, and thin corpus callosum were linked to this locus. In contrast, Boukhris et al. (12) studied Tunisian autosomal recessive HSP subjects (not selected for corpus callosum thinning) and found linkage to the SPG11 locus in seven of 38 families (18.4%). Similarly, Stevanin et al. (242) analyzed the SPG11/spatacsin gene coding sequence in 43 autosomal recessive families and 33 isolated patients and identified mutations in 41% of subjects with spastic paraplegia and thin corpus callosum, but only in 4.5% of subjects with spastic paraplegia and cognitive impairment who did not have thin corpus callosum.

**119.1.13.1 “Typically Uncomplicated” Autosomal Recessive HSP.** Whereas 12 of 20 genetic types of autosomal dominant HSP are “typically uncomplicated” (Table 119-1), only five (SPG5, SPG28, SPG29, and SPG48) of 26 genetic types of autosomal recessive HSP are “typically uncomplicated” (Table 119-1), with the caveat that since very few kindreds with each of these HSP have been described, the full phenotypic spectrum may not be completely known.

**119.1.13.2 “Variably Complicated” Autosomal Recessive HSP: SPG7, SPG11, SPG27.** These autosomal recessive types of HSP are “variably complicated” insofar as the “complicating” features are *variably present* in some but not all affected individuals. The fact that some subjects with these types of HSP have “uncomplicated” spastic paraplegia (even in families in which other individuals have “complicated” spastic paraplegia syndromes) must be considered when providing genetic counseling and prognosis.

Subjects with SPG11 HSP may demonstrate either mild or severe syndromes (243) of uncomplicated HSP; HSP with mental retardation but normal corpus callosum (244), or more frequently, HSP associated with thin corpus callosum, mental retardation, upper extremity weakness, dysarthria, and nystagmus (240,241). Some SPG11 subjects have distal muscle atrophy and retinal pigmentary abnormality consistent with “Kjellin syndrome,”

discussed in the following section (245). For additional descriptions of SPG11 HSP, see (153,170,242–251). Variant presentations of SPG11 mutation as juvenile parkinsonism (252) and juvenile ALS (253) are discussed in the following.

Similarly, some subjects with autosomal recessive SPG7 HSP (due to paraplegin gene mutations, discussed in Section 119.5.2) have uncomplicated HSP and others have additional neurologic abnormalities (155,239) including dysarthria, dysphagia, optic disc pallor, axonal neuropathy, and evidence of “vascular lesions”, cerebellar atrophy, or cerebral atrophy on cranial MRI (254).

Subjects with SPG27 HSP exhibit either uncomplicated, adult-onset spastic paraplegia or spastic paraplegia associated with dysarthria (32). For additional descriptions of SPG7 HSP see (76–79).

Only two families with autosomal recessive SPG27 HSP have been described. The SPG27 locus was identified by Lossos et al. (255) who reported seven affected subjects in French–Canadian family in which uncomplicated spastic paraplegia began between ages 25 and 45 years. In contrast, the Tunisian family linked to the SPG27 locus reported by Ribai et al. (256) had a childhood-onset disorder in which spastic paraplegia was accompanied (to variable extent) by ataxia, dysarthria, mental retardation, sensorimotor polyneuropathy, facial dysmorphism, and short stature.

**119.1.13.3 “Typically Complicated” Autosomal Recessive HSP.** Among 19 types of “typically complicated” HSP (see Table 119-1), the most common additional neurologic impairments are (1) peripheral motor-sensory neuropathy, distal muscle wasting, or sensory neuropathy (occurring in 13 types); (2) mental retardation, dementia (or both mental retardation and dementia, occurring in 12 types); (3) dysarthria (occurring in seven types); (4) ataxia and/or cerebellar atrophy (occurring in five types); (5) symptomatic upper extremity involvement (occurring in five types); (6) optic atrophy, maculopathy, or cataract (occurring in four types); and (7) thin corpus callosum (occurring in three types) and brain white matter abnormalities (occurring in three types). Some of these types of HSP conform to named syndromes.

*Mast syndrome* refers to SPG21 HSP (due to maspardin gene mutations) in which spastic paraplegia is associated with dementia, cerebellar and extrapyramidal deficits, and white matter abnormalities (162).

*Kjellin syndrome.* Kjellin (257) described an autosomal recessive disorder characterized by childhood-onset, progressive spastic paraplegia that is accompanied by pigmentary retinopathy, mental retardation, dysarthria, dementia, and distal muscle atrophy. Huges et al. (258) studied two families with Kjellin syndrome and identified linkage to a then novel locus on chromosome 14q, designated SPG15. Recently, SPG15 HSP has been shown to be due to Spatzin gene mutation (259). Subsequently, Kjellin syndrome was identified in subjects with SPG11

HSP (245,260), recently shown to be due to Spatacsin gene mutation (251). It is noteworthy that the full manifestations of Kjellin syndrome are not constant features of either SPG11/spatacsin or SPG15/spatzin gene mutations but instead are variably present in subjects with these types of HSP (258,259).

*Spastic Paraplegia as Part of a Neurocutaneous Syndrome.* Sjögren–Larsson syndrome (261,262) is an autosomal recessive disorder characterized by congenital ichthyosis, mental retardation, and spastic diplegia. Sjögren–Larsson syndrome is due to mutations in the SALDH3A2 gene that encodes FALDH. SPG23 HSP is characterized by childhood-onset spastic paraplegia and cutaneous pigment abnormality (263).

*SPOAN syndrome* is characterized by infantile spastic paraplegia associated with progressive optic atrophy, neuropathy, dysarthria, and progressive joint and spine deformities (118).

*HSP with thin corpus callosum* was initially recognized as a frequent (but not constant) feature of SPG11 (159,165–169). Subsequently, it was recognized that thin corpus callosum is not unique to SPG11 but is also a frequent or variable feature of additional types of autosomal recessive HSP [SPG7, SPG15, SPG21, SPG32, SPG47, and the syndrome “HSP with thin corpus callosum and epilepsy” (153,154)]. Thin corpus callosum has also been reported in autosomal dominant SPG3A and SPG4 HSP, both of which are typically “uncomplicated.” Thin corpus callosum in SPG11 HSP is frequently (but not always) associated with cognitive impairment (characterized in two subjects by Siri et al. (170)). Similarly, thin corpus callosum in other types of HSP is not always associated with cognitive impairment (105).

*Autosomal Recessive HSP with Distal Muscle Atrophy (“Troyer Syndrome”) and/or Peripheral Motor Neuropathy.* Autosomal recessive HSP associated with distal muscle atrophy was initially described in Amish families (264). Designated “Troyer syndrome”, this progressive spastic paraplegia syndrome was associated with not only distal muscle atrophy, but also short stature, mental retardation, and dysarthria (265). The disorder in these families was subsequently linked to the SPG20 locus and causative mutations in a novel gene (designated “Spartin” for spastin-related, autosomal recessive troyer syndrome) was discovered (266).

Subsequently, distal muscle wasting or motor neuropathy in at least some subjects has been reported with five other genetic types of autosomal recessive HSP: SPG11, SPG14, SPG15, SPG26, SPG39, and SPG43. SPG11 has a variety of presentations, most commonly associated with thin corpus callosum, although it may also exhibit pigmentary retinopathy, mental retardation, dysarthria, dementia, and distal muscle atrophy and conform to Kjellin syndrome (discussed above). SPG14 HSP, described in three subjects in an Italian family, was associated with mental retardation and motor neuropathy (distal atrophy per se was not mentioned) (267). SPG15

has been described in 13 families of Irish, Arabic, and Tunisian descent (258,259,268,269). Some of these subjects exhibited distal muscle atrophy, pigmented retinopathy, mental retardation, and dementia (258,259,270) and conform to “Kjellin syndrome,” discussed above. Recently, ZFYVE26 gene mutations have been identified in SPG15 HSP subjects (259). SPG26, in five siblings from a single, consanguineous Bedouin family, is described as childhood-onset progressive spastic paraplegia associated with distal amyotrophy in both upper and lower limbs (with normal nerve conduction studies), dysarthria, and variable intellectual impairment (271). Meilieur et al. (9) described two sisters from Mali, symptom onset seven and 12 years, progressive spastic paraplegia with atrophy of intrinsic hand muscles and dysarthria (one sister). Genetic analysis identified a linkage to novel HSP locus (19p13.11-q12) designated SPG43.

Distal muscle atrophy is a characteristic of SPG39 due to neuropathy target esterase (NTE) gene mutation (272,273). SPG39 HSP was described in six subjects from two unrelated families and characterized by childhood onset, slowly progressive spastic paraplegia that becomes associated in adolescence with progressive, ultimately severe wasting of intrinsic hand and distal lower extremity muscles. Peripheral motor neuropathy with normal sensory nerve conduction studies was demonstrated in SPG39 HSP (also known as NTE-related motor neuron disease) (272,274). SPG39 patients do not have additional features of short stature, mental retardation, and dysarthria, which are present in many SPG20 HSP subjects (272,275).

SPG14, SPG26, and SPG43 HSP have each been described in single families.

*X-linked HSP* is also genetically heterogeneous. Like autosomal dominant HSP and autosomal recessive HSP, X-linked HSP exists as both “uncomplicated” (276) and “complicated” spastic paraplegia syndromes. SPG16 HSP begins in childhood and may manifest either as uncomplicated HSP or as spastic paraplegia associated with aphasia, visual impairment, and mental retardation (277,278).

**119.1.13.4 L1CAM Mutations: X-linked Hydrocephalus, MASA Syndrome, and X-linked Spastic Paraplegia.** SPG1 HSP is an Xq28-linked HSP associated with mental retardation and adducted thumbs and is due to mutations in the neuronal cell adhesion molecule L1CAM. In addition to X-linked spastic paraplegia with mental retardation, and adducted thumbs, mutations in the L1CAM gene also cause X-linked hydrocephalus, MASA syndrome (mental retardation, aphasia, shuffling gait, adducted thumbs), and CRASH syndrome (corpus callosum hypoplasia, retardation, adducted thumbs, spastic paraparesis, and hydrocephalus) (151,279,280).

**119.1.13.5 PMD Is Allelic with SPG2 HSP; PMLD Is Allelic with SPG44 HSP.** SPG2 HSP is due to mutations in the PLP gene. The PLP gene encodes an intrinsic

myelin protein (281). In addition to SPG2 HSP, mutations in the PLP gene cause PMD, an X-linked, infantile-onset, severe neurologic disorder due to abnormal myelin formation. Often, subjects with Xq21-22-linked HSP have MRI evidence of central white matter disturbance (144,282,283). It is noteworthy that the underlying pathology for slowly progressive spastic paraplegia in SPG2 is considered to represent axonal degeneration rather than demyelination despite the fact that SPG2 is due to abnormality in an intrinsic myelin protein (284). This is supported by murine models of SPG2 HSP that show axonal degeneration as the consequence of oligodendroglial/myelin abnormality (285,286).

The basis for clinicopathologic differences between PLP mutations that result in PMD and X-linked HSP is not completely established. In some patients, phenotype variations correlate with specific PLP gene mutations associated with each disorder (287). In other families, both early-onset severe Pelizaeus–Merzbacher leukodystrophy and later-onset insidiously progressive spastic paraplegia have occurred in individuals with precisely the same PLP mutation.

Despite thorough investigation, some subjects linked to Xq22 do not appear to have PLP gene mutations. This raises the possibility of an additional gene at this locus for X-linked spastic paraplegia (277).

As noted above, PMD is an X-linked, hypomyelinating, congenital leukodystrophy due to PLP gene mutation. Recently, mutations in two other genes have been shown to cause autosomal recessive (rather than X-linked) forms of this syndrome. Specifically, PMLD are associated with mutation in the ARS-interacting multifunctional protein 1 (AIMP1) gene (identified in consanguineous Israeli Bedouin family) (288) as well as mutations in the GJA12 gene, which encodes gap junction protein alpha 12 (also known as connexin 47) (289). Like PLP, GJA12/connexin 47 is an important factor in central and peripheral myelin formation.

Just as PMD is allelic with a more slowly progressive disorder (SPG2 HSP), so too does PMLD due to GJA12/connexin 47 mutation. Recently, Orthmann-Murphy, et al. (290) identified homozygous GJA12 mutations in three subjects from a possibly consanguineous, Italian kindred. Affected subjects had symptom onset in the first or second decade, very slow progression, mild to severe gait disturbance, and variable involvement of upper extremity, speech, cerebellum, and cognition. EMG and nerve conduction studies were normal. Brain MRI was consistent with hypomyelination. This syndrome is designated SPG42 HSP.

The findings that PMD is allelic with SPG2 HSP, and that PMLD is allelic with SPG42 have three important implications. First, they indicate that infantile-onset leukodystrophies may manifest as later-onset, milder phenotypes. (The concept that infantile-onset metabolic disorders may manifest in adulthood as relatively more slowly progressive disorders is well known and illustrated

by other notable examples: adrenoleukodystrophy/adrenomyeloneuropathy, Tay–Sachs disease/partial hexosaminidase deficiency, and infantile Krabbe/late-onset Krabbe disease.) Second, these disorders underscore the concept that primary myelin abnormalities may cause axonopathy (291). In this regard, mouse models of SPG2 HSP exhibit either axonal degeneration (consistent with SPG2 HSP) or demyelination (consistent with PMD) depending in part on the nature of the PLP gene disturbance (284,292,293). And finally, these syndromes highlight the growing awareness that myelin abnormalities are present in a number of forms of HSP (discussed below). Note in particular that mutation of the bovine SPG4/spastin gene causes congenital dysmyelination.

*Allan–Herndon–Dudley (AHD) syndrome (SPG22)* is an X-linked disorder characterized by congenital onset, neck muscle hypotonia in infancy, mental retardation, dysarthria, ataxia, spastic paraplegia, and abnormal facies. Recently, Schwartz et al. (294) showed that AHD patients had mutations in the SLC16A2 gene that encodes monocarboxylate transporter-8 (MCT8). Previously, mutations in this gene were reported in males with hypotonia, involuntary movements, and mental retardation (295,296). MCT8 is a thyroid hormone transporter. MCT8 mutations may be associated with increased serum triiodothyronine (T3) (295).

## 119.2 MATERNAL (MITOCHONDRIAL GENOME) INHERITANCE

### 119.2.1 Mitochondrial ATP6 Gene

Verny et al. (212) reported a late-onset spastic paraplegia-like disorder that affected five subjects of a family (a mother, all three of her daughters, and two of her four sons). Although there was extreme variability in symptom severity and disability, lower extremity pain was a common feature. One individual had slowly progressive spastic paraplegia and lower extremity pain that began at age 30 leading to wheelchair dependence in his late 40s. This individual also had diabetes mellitus, hypertrophic cardiomyopathy, associated with supraventricular arrhythmia and ataxia (excess alcohol may have been a contributing factor). Two individuals had painful legs, mild sensory loss, but only minimal disability. One subject had axonal neuropathy and yet another had moderate spastic paraplegia, lower extremity pain, and reduced vibratory sensation.

The authors discovered mutation (m.9176 T>C) in the mitochondrial ATP6 gene and showed that the clinical severity of the disease correlated with the biochemical and assembly defects of the ATP synthase (212). This same mitochondrial ATP6 gene mutation had previously been reported in Leigh syndrome, thus expanding the phenotypic spectrum associated with this mutation and implicating the effect of modifying genes and/or environmental factors.

### 119.2.2 “Apparently Sporadic” Spastic Paraplegia

Many subjects who have all the signs and symptoms of uncomplicated HSP have no similarly affected relatives. Despite thorough neurodiagnostic analysis, alternative disorders are not identified. This is the syndrome of ASSP (297). In our database of more than 300 unrelated HSP syndrome subjects, ~25% conform to ASSP. The disorders among ASSP syndrome subjects are heterogeneous and may include both nongenetic disorders (e.g., copper-deficient myelopathy or paraneoplastic disorders), early stages of PLS and ALS, and those for whom the disorder is autosomal recessive HSP, X-linked HSP, or autosomal dominant HSP (with absent family history due to incomplete or inaccurate family information, late age-of-symptom onset, incomplete penetrance, *de novo* mutation, or mistaken paternity). Depending on the extent of genetic testing, ~5–18% of individuals with ASSP have been shown to have a mutation in an HSP gene (298–301) including SPG4/spastin mutations, which are generally associated with autosomal dominant HSP with high genetic penetrance (186,237,297). Undoubtedly, this figure will increase as additional HSP genes are available for evaluation in ASSP syndrome subjects. Identifying an HSP gene mutation in subjects with ASSP would change the diagnosis to HSP and have important implications for genetic counseling (discussed below).

Other than family history, there are no clinical features (such as age-of-symptom onset, rate of symptom progression, or extent of disability) that distinguish uncomplicated spastic paraplegia subjects with (autosomal dominant, recessive, or X-linked HSP) from those with uncomplicated ASSP. A cautiously optimistic, wait-and-see approach is advised regarding the prognosis of such individuals. After many years, a relative may become similarly affected and the disorder will be recognized as HSP. Some individuals, however, will continue to have slowly progressive spastic weakness that is confined to the lower extremities and that is clinically indistinguishable from uncomplicated HSP. Other individuals, however, will develop upper extremity and corticobulbar muscle weakness and be re-classified as PLS (discussed below) (85). For still other individuals, “apparently sporadic HSP” represents an early phase of ALS (302–306).

### 119.2.3 Penetrance in Autosomal Dominant HSP

The frequency with which obligate carriers of autosomal dominant HSP pathogenic gene mutations exhibit the disorder is age-dependent, very high, but incomplete. Incomplete genetic penetrance has been reported for SPG4 (61), SPG8 (31), and SPG3A HSP (307,308). Mitne-Neto et al. (309) described sex-dependent penetrance (earlier age-of-symptom onset in males) in subjects with SPG4 HSP due to tandem duplication of SPG4/spastin exon 10–12.

As yet, too little information exists to know whether reduced penetrance is more frequent for certain mutations in these genes than for other mutations. Fonknechten et al. (61) provide the best estimate of genetic penetrance for SPG4 HSP (due to spastin gene mutations, discussed below). They examined the frequency of clinical signs and symptoms among 238 obligate gene carriers (those with spastin gene mutations) from 44 autosomal dominant HSP kindreds. The age-of-symptom onset varied from 0 to 74 years (mean  $\pm$  standard deviation was  $29 \pm 17$  years). Among 238 subjects from SPG4-linked kindreds shown to have mutations, only 179 (75%) were aware of having symptoms (61). They observed clinical symptoms and signs of HSP in 85% individuals with spastin gene mutation who were older than 40 years (61).

In general, incomplete penetrance in HSP is observed more often in kindreds in whom age-of-symptom onset extends over a broad range into senescence, than in families with uniform symptom onset in early childhood. Careful neurologic examination of many asymptomatic obligate gene mutation carriers often demonstrates lower extremity corticospinal tract disturbance (hyperreflexia and often extensor plantar response). For example, Durr et al. (82) studied 12 SPG4-linked kindreds. Among 93 gene carriers, 32 (34%) were asymptomatic with very few exceptions; neurologic examination of asymptomatic gene carriers disclosed lower extremity corticospinal tract signs. Nonetheless, incomplete penetrance has also been reported for SPG3A HSP, which typically begins in early childhood (108,234,307,308).

For some asymptomatic obligate gene carriers, lower extremity deep tendon reflexes and the remainder of the neurologic examination are entirely normal. Depending on their age, and the age-of-symptom onset within the family, these individuals may be considered either still at risk of developing the disease or genuinely nonpenetrant. For example, Hedera et al. (31) reported a chromosome 8q-linked autosomal dominant HSP kindred in which age-of-symptom onset ranged from 22 to 60 years (mean  $37.3 \pm 12.2$  SD). One obligate gene carrier was entirely asymptomatic and had a normal neurologic examination at age 60. It is uncertain whether this individual is a rare example of nonpenetrance or whether she will ultimately develop HSP. Similarly, the extended kindred reported by Cooley et al. (310) contained one elderly asymptomatic carrier of autosomal dominant, uncomplicated HSP.

HSP's apparently high degree of genetic penetrance may include an ascertainment bias. Autosomal dominant HSP is more readily diagnosed in large kindreds for whom the disorder is highly penetrant. This could contribute to overrepresentation of highly penetrant HSP kindreds in published studies. Unless genetic testing is performed, a mutation in an HSP gene that is known or likely to be pathogenic is discovered, and unaffected family members tested, it is not possible to estimate

genetic penetrance in kindreds consisting of affected siblings (with unaffected parents) since this could represent an autosomal recessive disorder or an autosomal dominant disorder with incomplete penetrance, or in kindreds consisting of an affected child, an affected parent, and unaffected grandparents since this could represent either incomplete penetrance (in a grandparent) or a new mutation (in a parent). Caution must be observed when providing genetic counseling for spastic paraplegia subjects with no previous family history in whom a pathogenic mutation for dominantly inherited HSP is found (but other family members not tested). In addition to *de novo* mutation, mistaken paternity, and incompletely ascertained family members, absence of previous family history could represent incomplete genetic penetrance (or late-onset and mild symptoms in some subjects).

In general, there is very limited information about the genetic penetrance of autosomal recessive and X-linked forms of HSP.

#### 119.2.4 Modifying Factors

HSP's genetic penetrance is age-dependent, and although high, it is not complete (discussed above). Moreover, there is often marked phenotype variability between subjects with the same genetic type of HSP and even between affected subjects in the same family who share the precise HSP gene mutation. Incomplete penetrance and marked phenotype variation between subjects with the same mutation implicate modifying factors (environmental and genetic) in the development, severity, and age at onset of lower extremity spastic weakness. There is one report (311) of a two generation kindred with autosomal dominant, uncomplicated HSP in which one of two monozygotic twins developed HSP. (Monozygosity was confirmed by testing 24 informative genetic markers.) Observations of discordancy between monozygotic twins and extreme variability in age-of-symptom onset and degree of disability among individuals in the same family who have the same HSP gene mutation indicate the effect of modifying factors (both genetic and nongenetic factors in the development of spastic paraplegia in HSP).

One source of modifying genes is variation in HSP genes themselves. This includes mutation-related variation in HSP gene transcript abundance (312,313) and HSP coding sequence polymorphisms. Svenson et al. (314) analyzed *benign* SPG4/spastin polymorphisms (S44L and P45Q) and showed that L44 and Q45 are each associated with a striking decrease in age at onset in the presence of the *pathogenic* mutations in SPG4/spastin's AAA domain. Schickel et al. (315) showed that spastin polymorphisms S44L, E43Q, and P45Q enhanced the stability of alternative spastin isoforms. They propose that the relative abundance of alternative spastin isoforms could ultimately influence the

phenotype by increasing competition of various spastin isoforms for interacting proteins, substrates, or oligomerization partners.

**119.2.4.1 Emerging HSP “Protein Interactome”.** One source of modifying factors is the proteins that interact directly with HSP proteins. Presently, nine of the 22 discovered HSP proteins interact directly with another HSP protein or share common interaction with a third protein (see Table 119-4). Indeed, Slabicki et al. (316) and Mannan et al. (47) evaluated spastin-interacting proteins and identified mutations in ZFYVE27 and KIAA0415 that cause SPG33 and SPG48 HSP, respectively. Direct interaction between HSP proteins raises the possibility that the phenotype in subjects with pathogenic mutation HSP gene mutations could be influenced by otherwise benign variation (including coding sequence polymorphisms, gene regulation, and copy number variants) in other HSP genes.

**119.2.4.2 HSP Genotype–Phenotype Correlation.** International efforts are underway develop a database of HSP gene mutations that lists, for each mutation in each HSP gene, specific phenotype parameters (age-of-symptom onset, genetic penetrance, associated neurologic or systemic impairments, extent of functional disability) as well as family history, ethnicity, and comorbid conditions (317). Once established, this database will provide information regarding the range of symptoms and functional severity. This information will guide prognosis and genetic counseling. By combining clinical information with *in silico*, *in vitro*, and *in vivo* models, the relative pathogenicity of novel HSP gene mutations can be assessed.

In a broad sense, however, the clinical phenotype associated with a given HSP gene mutation is influenced by a myriad of factors beyond the discrete mutation itself. The clinical phenotype of HSP reflects the composite outcome of numerous factors including (1) genetic regulation (e.g., regulation of the HSP gene bearing the pathogenic mutation, regulation of other HSP genes, regulation of other genes influencing axon growth and maintenance, genetic regulation of inflammatory response to antigens liberated in neurodegeneration); (2) genetic polymorphisms (including copy number variants) in the HSP gene bearing the pathogenic mutation, other HSP genes, other genes influencing or compensating for axon degeneration; (3) epigenetic influences (potentially, age-, diet-, or environmentally related gene silencing of the aforementioned genes); (4) neuroplasticity (in turn affected by age, diet, exercise, and self-specific (idiotypic) combinations of genetic factors including those mentioned above); (5) environmental factors (such as exposure to neurotoxins as well as the influence of diet and exercise); (6) general health (including coexistent medical conditions, quality of sleep, pain, depression); and (7) age (including chronobiologic effects on neurologic and immunologic function).

### 119.3 ASSOCIATION OF HSP GENE MUTATIONS WITH SYNDROMES OTHER THAN SPASTIC PARAPARESIS

#### 119.3.1 BSCL2/Seipin Mutations Cause Autosomal Dominant HSP (SPG17), Charcot–Marie–Tooth Type 2, and Distal Hereditary Motor Neuropathy Type V

These syndromes vary in the degree of upper motor neuron involvement (i.e., there is significant spasticity and hyperreflexia in the SPG17 HSP syndrome), lower motor neuron (i.e., there is significant atrophy in the distal hereditary motor neuropathy syndrome), and peripheral axonal neuropathy [which is marked in Charcot–Marie–Tooth (CMT) type 2] (318).

*BSCL2/Seipin mutations cause congenital generalized lipodystrophy type 2 (CGL2)*, manifesting as severe lipoatrophy, insulin resistance, hypertriglyceridemia, and mental retardation (318,319). It is important to point out that whereas CGL2 is an autosomal recessive disorder due to homozygous or compound heterozygous BSCL2/Seipin gene mutation, SPG17 HSP is an autosomal dominant disorder due to heterozygous BSCL2/Seipin gene mutation (41).

#### 119.3.2 Juvenile Parkinsonism

Anheim et al. (252) described juvenile parkinsonism in two subjects from a consanguineous Turkish family who had a novel SPG11/Spatacin mutation (homozygous for c.704\_705delAT, p.H235RfsX12). In the first subject, parkinsonism was the initial feature including marked rest tremor, moderate akinesia, and rigidity. At the time of initial examination (age 12) the patient had brisk reflexes, bilateral extensor plantar response, and reduced vibration sensation. Despite initial benefit from levodopa, both extrapyramidal and pyramidal syndromes worsened progressively and the patient became wheelchair-dependent at age 22. At age 15, the second subject had spastic paraparesis, decreased vibration sensation, and dementia. This was followed by parkinsonism at age 16 that did not respond to levodopa. Both extrapyramidal and pyramidal syndromes worsened progressively. As it frequently occurs in SPG11 HSP, each subject was mentally retarded and had thin corpus callosum and axonal neuropathy.

Independently, Micheli et al. (320) described two Korean siblings with thin corpus callosum (a frequent feature of SPG11 and several other types of HSP), one of whom had primarily levodopa-responsive parkinsonism, and the other had progressive spastic paraplegia. Genetic testing was not performed. Extrapyramidal rigidity in the hands has also been described in one subject with SPG15 HSP (259), which also is associated with thin corpus callosum.

TABLE 119-4 HSP Proteins

HSP Gene/Protein	Functions	References
SPG1/L1CAM	Integral membrane glycoprotein, cell adhesion molecule in the immunoglobulin superfamily; mediates cell-to-cell and cell-to-matrix attachment; functions include guidance of neurite outgrowth during development, neuronal cell migration, and neuronal cell survival. <i>Interacts with Bone Morphogenic protein (affects L1CAM gene regulation)</i>	(451,454,455)
SPG2/PLP	Proteolipid protein (PLP) is an integral myelin protein expressed in oligodendroglia and Schwann cells but not in neurons	(461)
SPG3A/atlastin	Dynamin family GTPase, interacts with HSP proteins spastin, NIPA1, and REEP1; involved in membrane fusion and severing; contributes to endoplasmic reticulum morphology. <i>Interacts with SPG4/spastin, REEP1, NIPA1, DP1/Yop1 p and reticulon families of ER-shaping proteins, HPK/GCK-like kinase (HGK) (a protein kinase in the c-Jun N-terminal kinase signaling pathway; Inhibits BMP signaling in Zebrafish model)</i>	(375–381,382,556,557)
SPG4/spastin	Cytosolic (and possibly nuclear) protein with AAA domain; (AAA domain is also present in paraplegin); interacts with microtubules and has microtubule severing properties; interacts with atlastin and REEP1 and contributes to endoplasmic reticulum morphology; mutations affect axonal transport. <i>Interacts with: SPG3A/Atlastin, SPG31/REEP1, SPG33/ZFYVE27, ESCRT-II complex associated CHMP1B, Reticulon 1 (endoplasmic reticulum protein), Reticulon 3, CREL5, COP55, Tubulin; inhibits bone morphogenic protein signaling</i>	(47,379,390,400,557–559)
SPG5/CYP7B1	Cytochrome P450-7B1 (CYP7B1) provides primary metabolic route for cholesterol derivatives dehydroepiandrosterone (DHEA) and related hydroxysteroids via 7 $\alpha$ -hydroxylation; and that in the liver; and an alternative route for cholesterol metabolism.	(418)
SPG6/NIPA1	“Not imprinted in Prader Willi/Angelman 1” (NIPA1): nine alternating hydrophobic-hydrophilic domains predicts integral membrane localization; NIPA1 binds to BMP-II receptor to inhibit BMP signaling; NIPA1 transcription is induced by low extracellular Mg <sup>++</sup> ; NIPA1 expression causes inwardly direct Mg <sup>++</sup> conductance. <i>Interacts with Type II bone morphogenic protein (BMP) receptor 2 (BMPRII) to inhibit BMP signaling and SPG3A/atlastin</i>	(400)
SPG7/paraplegin	Mitochondrial metalloprotease, involved as protein chaperone in mitochondrial protein quality control. <i>Interacts with AFG3L2 (mutations cause SCA type 28)</i>	(407,423)
SPG8/Strumpellin (KIAA0196)	KIAA0196/Strumpellin, mutations may be pathogenic through protein aggregation: Strumpellin binds to valosin-containing protein (VCP; also known as p97, TER ATPase and Cdc48 p); VCP-positive inclusions occur in a wide variety of neurodegenerative disorders including Parkinson’s disease, Lewy body disease, Huntington’s disease, amyotrophic lateral sclerosis, and SCA type III (Machado–Joseph disease); Strumpellin may also regulate actin dynamics through its interaction with WASH; <i>interacts with Valosin-containing protein (VCP; also known as p97, TER ATPase and Cdc48 p); WASH, a Wiskott–Aldrich syndrome protein (WASP) family member, via SWIP (Strumpellin and WASH interacting protein (WASH localizes to endosomal subdomains and regulates endocytic vesicle scission in an Arp2/3-dependent manner).</i>	(560)
SPG10/KIF5A	Kinesin heavy chain (KIF5A) a molecular motor subunit that participates in the intracellular movement of organelles and macromolecules	(465)
SPG11/Spatacsin	Unknown function; spatacsin is a component of a protein complex that includes two other HSP proteins, SPG15/ZFYVE26 and SPG48/KIAA0415 (316), suggesting that these forms of HSP may share similar molecular pathogenesis. <i>Interacts with SPG48/KIAA0415, SPG15/ZfyVe26, C200RF29, DKFZp761E198</i>	(316)
SPG13/KIF5A	HSPD1 gene encodes Chaperonin 60 (also known as heat shock protein 60, HSP60), the large subunit of the mitochondrial Hsp60/Hsp10 chaperonin complex; functions in mitochondrial protein quality control (binding and sequestration, and refolding of unfolded proteins)	(414)
SPG15/Spastizin (ZFYVE26)	FYVE-domain proteins have diverse functions including membrane trafficking, signal transduction, regulating the cytoskeleton, and serving as phosphatidylinositol 3-phosphate (PtdIns3P) phosphatases. Spastizin colocalizes with ER and endosome markers and is a component of a protein complex that includes two other HSP proteins, SPG11/spatacsin and SPG48/KIAA0415. <i>Interacts with SPG11/Spatacsin and SPG48/KIAA0415</i>	(259,316,425)

TABLE 119-4 HSP Proteins—cont'd

HSP Gene/Protein	Functions	References
SPG17/BSCL2	BSCL2/seipin: Endoplasmic reticulum transmembrane protein; mutations appear pathogenic through induction of endoplasmic reticulum stress-mediated apoptosis	(318,415,416)
SPG20/spartin	Spartin: N-terminal region similar to spastin; homologous to proteins involved in the morphology and trafficking of endosomes; also localizes to mitochondria; interacts with Eps 15, a protein known to be involved in endocytosis and the control of cell proliferation, suggesting that spartin may be involved in endocytosis, vesicle trafficking, or mitogenic activity; spartin promoter hypermethylation is associated with cytokinesis arrest in colorectal carcinoma. <i>Interacts with GRP78, GRP75, ubiquitin, and the E3 ubiquitin-protein ligases AIP4/Itch and AIP5/WWP1, and; nucleolar protein "nucleolin"; inhibits BMP signaling</i>	(358,400,427,428,431,561,562)
SPG21/masparidin	Appears to be a cytosolic protein partitioned between the cytosol and vesicles of the endosomal/trans-Golgi network; may play a role in endosomal trafficking; may be similar to a noncatalytic $\alpha/\beta$ hydrolase protein NDRG1, mutations in which cause peripheral neuropathy with early axonal involvement. <i>Interacts with Aldehyde dehydrogenase ALDH16A1</i>	(162,432)
SPG22/MCT8	Monocarboxylate transport 8 (MCT8) is a thyroid hormone transporter, results in elevated serum triiodothyronine (T3) levels	(462)
SPG31/REEP1	Receptor expression enhancing protein 1 (REEP1), structurally related to the DP1/Yop1p family of endoplasmic reticulum-shaping proteins; required for ER network formation in vitro; forms complexes with atlastin and spastin within endoplasmic reticulum; also binds to microtubules and promotes ER alignment along the microtubule cytoskeleton in vitro. <i>Interacts with SPG3A/Atlastin and SPG4/spastin</i>	(379)
SPG33/ZFYVE27	ZFYVE27/protrudin has a role in Rab11-mediated membrane trafficking and promotes neurite outgrowth. <i>Interacts with SPG4/spastin and RAB11</i>	(47,74)
SPG35/FA2H	Fatty acid 2-hydroxylase (FA2H) in oligodendroglia catalyzes the 2-hydroxylation of myelin galactolipids, galactosylceramine, and sulfatide, and therefore helps determine myelin lipid content	(563)
SPG39/NTE	Neuropathy target esterase (NTE) is a phospholipase localized to ER membranes; may reduce cytotoxic lysophosphatidylcholine; implicated in toxic organophosphorus compound induced delayed neurodegeneration (OPIDN); may function to regulate cyclic AMP-dependent protein kinase. <i>Interacts with Cyclic AMP-dependent protein kinase (in Drosophila)</i>	(434–443,445,446)
SPG42/SLC33A1	SLC33A1 is an acetyl CoA transporter that moves acetyl-CoA into the Golgi apparatus where it may be transferred to sialyl residues of gangliosides and glycoproteins	(53)
SPG44/GJA12/GJC2	Gap junction protein (GJA12/GJC2) also known as connexin47 (Cx47); important factor in formation of specialized channels ("gap junctions") between cells that allow selective movement of ions and metabolites between adjacent intracellular compartments	(288,290,447)
SPG48/KIAA0415	KIAA0415 encodes a putative helicase involved in DNA repair; Interacts with SPG11/Spatacsin, SPG15/ZFYVE26, C20ORF29, DKFZp761E198	(316)
Cct5	Epsilon subunit of the cytosolic chaperonin-containing t-complex peptide-1 (Cct5); contributes to the protein folding and assembly of a wide variety of cytosolic proteins including actin and tubulin	(119)
Mitochondrial ATP6 gene	Synthesis of ATP (from ADP) in mitochondria is coupled to translocation of protons from the mitochondrial matrix to specific intermembrane sites. Mitochondrial ATP6 forms a channel through which protons flow back from intermembrane sites into the mitochondrial matrix; and is thus an important factor in mitochondrial ATP production	(212,564)

### 119.3.3 Sensory Neuropathy

As noted above, SPG3A/atlastin mutation p.Asn355Lys was associated with the syndrome autosomal dominant HSN 1 rather than with the syndrome of HSP (114). Sensory neuropathy occurs with spastic paraplegia in two additional syndromes, (SPOAN syndrome, linked to chromosome 11q23) (118) and “mutilating sensory neuropathy with spastic paraplegia” due to *Cct5* gene mutation (119–122).

### 119.3.4 HSP-Related Disorders

ALS is often an important consideration in the differential diagnosis of subjects with progressive spastic paraplegia, particularly when there is no clear family history or presence of a causative gene mutation to support the diagnosis of HSP. “Upper motor neuron predominant” ALS may begin with lower extremity spastic weakness, and particularly in young individuals, be slowly progressive (192,193,195).

For ~10% of subjects, ALS is a familial disorder. Mutations in a number of genes (321,322) have been identified in both familial and “apparently sporadic” ALS subjects. The discovery that ALS can have multiple separate causes (mutations in different genes) indicates that ALS, like HSP, is a clinicopathologic syndrome that can result from molecularly distinct inciting abnormalities.

Neuropathologic features of ALS (degeneration of corticospinal tract axons, loss of anterior horn cells, degeneration of peripheral motor axons, and degeneration of pyramidal neurons in the motor cortex) overlap those of HSP (degeneration of corticospinal tract axons with variable peripheral motor axon degeneration, variable and mild degeneration of anterior horn cells, and degeneration of *fasciculus gracilis* fibers). As previously noted, distal muscle atrophy and peripheral motor neuropathy are typical or variable features of many forms of HSP (see Table 119-1). Indeed, at times, lower motor neuron involvement in some subjects with HSP meet diagnostic criteria for ALS. For example, the combination of spastic paraplegia and distal muscle atrophy in some (though not all) subjects with SPG11 HSP meet criteria for juvenile ALS (253). Although a case of ALS occurring with SPG4/spastin mutation (c.304\_309dupGCCTCG in exon 1) has been described (71), it is difficult to know if this is an unusual form of ALS with prolonged survival (more than 40 years), or an unusual form of SPG4 HSP with bulbar muscle and marked upper extremity involvement and distal wasting (71). In addition, muscle wasting in subjects with SPG39/NTE mutation (272), and rarely with SPG3A/atlastin mutation (109), may meet ALS diagnostic criteria.

Rather than concluding that these HSP gene mutations cause ALS, such cases may reflect the inclusive nature of *El Escorial* criteria for diagnosing ALS. Summarized in the Amyotrophic Lateral Sclerosis Association website ([http://www.alsa.org/assets/pdfs/fyi/criteria\\_for\\_diagnosis.pdf](http://www.alsa.org/assets/pdfs/fyi/criteria_for_diagnosis.pdf)),

these criteria state that “Definite ALS is defined on clinical grounds alone by the presence of upper motor neuron (UMN) as well as lower motor neuron (LMN) signs in the bulbar region and at least two of the other spinal regions or the presence of UMN and LMN signs in three spinal regions. The important determinants of diagnosis of definite ALS in the absence of electrophysiological, neuroimaging and laboratory examinations are the presence of UMN and LMN signs together in multiple regions.” Many subjects with complicated HSP associated with distal muscle atrophy or motor neuropathy may fulfill these criteria. Nonetheless, the insidiously progressive course (over decades) of bilaterally symmetric, lower extremity spastic weakness usually distinguished HSP syndromes (uncomplicated or complicated) from typical, adult-onset ALS syndromes (familial or sporadic), which generally progress more rapidly (e.g., over 1–5 years,) and often exhibit markedly asymmetric, unilateral, or single-limb weakness. One caveat, however, are juvenile forms of ALS, in which more gradually progressive and symmetric weakness and spasticity may be similar to some complicated HSP syndromes.

Recent results of a study of genome copy number variants in ALS are intriguing from the standpoint of potential HSP–ALS relationship. This study (323) analyzed genome copy number variants in 1875 ALS subjects and 8731 control subjects. Although this study did not find evidence for a difference in global copy number variant between ALS and control subject cohorts, two loci met criteria for follow-up investigation: the DPP6 locus (which has already been implicated in ALS pathogenesis) and the 15q11.2 locus, containing NIPA1, mutations in which cause autosomal dominant SPG6 HSP. Clearly, NIPA1 and the molecular cascade with which it interacts warrant further investigation in ALS pathogenesis.

PLS, independently described by Erb and Charcot (324), originally referred to a clinicopathologic syndrome in which progressive spastic weakness involving the lower extremities, eventually the upper extremities and corticobulbar muscles (325,326), was associated with degeneration of corticospinal and corticobulbar tracts. More recently, it is recognized that rather than being a single etiologic entity, the PLS syndrome (insidiously progressive spastic weakness involving lower and upper extremities, speech, and swallowing) can be a feature of genetically heterogeneous disorders. Although for the vast majority of subjects, PLS occurs as an “apparently sporadic” disorder (without known family history), both an autosomal recessive form of juvenile PLS and a family with an autosomal dominant PLS syndrome have been described. Like HSP, neuropathologic analysis of PLS shows axonal degeneration of corticospinal tracts with general preservation of the anterior horn cells. Autopsy of some, but not all (326), PLS subjects revealed decreased number of Betz cells in layer 5 and decreased number of pyramidal tract neurons in layers 3 and 5 of the precentral gyri (325,327). As noted above, atrophy

or decreased number of Betz cells has been described in HSP (172,173). For recent reviews of PLS and HSP, see (85,304–306,328).

Classically, PLS is distinguished clinically from HSP on the basis of (1) inheritance: PLS is usually an “apparently sporadic” disorder (although, as noted above, an autosomal recessive juvenile form and a family with dominantly inherited PLS have been described (329,330)); and (2) symptomatic upper motor neuron deficits involving upper extremities, speech, and swallowing (whose presence makes PLS discernible from “uncomplicated,” “apparently sporadic” HSP but not necessarily separable from some complicated forms of HSP (Table 119-5)). On the other hand, early stages of PLS (prior to development of upper extremity weakness, dysarthria, and dysphagia) may not be distinguished from “apparently sporadic” HSP (discussed above). Previously (303), assessment of distal lower extremity dorsal column function (by vibratory sensation in the toes and SSEPs) was considered useful to distinguish HSP (considered to be a central nervous system, motor-sensory axonopathy often involving mild lower extremity dorsal column impairment) from PLS (considered to be a pure upper motor neuron degenerative process sparing dorsal column

fibers). Recently, however, Brugman et al. (85) showed that a subset of PLS subjects had lower extremity dorsal column impairment. Involvement of dorsal columns in a subset of PLS subjects both challenges the concept that this clinical parameter can distinguish HSP from PLS and may expand our understanding of the PLS syndrome to include mild, sensory (dorsal column) involvement.

**119.3.4.1 Juvenile PLS and Familial PLS.** We (J. K. Fink, unpublished observations) and others (329,331) have observed infantile and early childhood-onset lower extremity spastic weakness among siblings that for several years was consistent with autosomal recessive uncomplicated HSP; and which was followed later by progressive involvement of the upper extremities, speech, and swallowing, consistent with the diagnosis of PLS. Such families in which PLS is transmitted as an autosomal recessive syndrome could be classified as either familial PLS or as a complicated form of HSP with upper extremity and bulbar muscle involvement (332–335).

Yang et al. (335) and Hadano et al. (336) identified mutations in the ALS2 gene (protein: “ALSin”) in juvenile onset autosomal recessive PLS. Depending on the particular ALSin gene mutation, subjects exhibited either a progressive upper motor neuron syndrome (spastic

**TABLE 119-5 Animal Models of Hereditary Spastic Paraplegia**

Spastic Gait (SPG)	Protein Name	Mouse	<i>Drosophila</i>	<i>Zebrafish</i>	<i>Caenorhabditis elegans</i>	Other

SPG39 (19p13)	Neuropathy target esterase (NTE)	(479)	(492,493,581)			
SPG42 (3q24-q26)	Acetyl CoA transporter (SLC33A1)			(53,570)		

weakness involving the upper and lower extremities, spastic dysarthria, and dysphagia) or also had lower motor neuron signs (e.g., muscle atrophy) consistent with slowly progressive ALS (335). The absence of detectable ALSin mutations in some families suggests that autosomal recessive familial PLS/juvenile ALS is genetically heterogeneous. For additional clinical and molecular features and animal models of ALS2/Juvenile PLS, see (337–340).

Chow et al. (330) described a French–Canadian kindred with an adult-onset (age 30–60 years), PLS syndrome (progressive spastic paraparesis, followed closely by spastic weakness of the upper extremities and later associated with spastic dysarthria and dysphagia). Subsequently, a genetic locus (4ptel-4p16.1) segregating with this disorder was identified (341). The possibility that genetic factors contribute to PLS in some subjects may be supported by the recent observation of FIG4 mutations in two subjects described as having PLS (342).

**119.3.4.2 Infantile Onset HSP and Familial Cerebral Palsy.** Nonprogressive lower extremity spastic weakness dating to infancy and unaccompanied by mental retardation or other neurologic abnormalities (“spastic diplegic cerebral palsy”) often occurs in the absence of obvious risk factors (such as prematurity, small size for gestational age, and multiple pregnancy, or intrauterine hypoxia) (343,344). A study performed in England and Sweden estimated that 2% of all cerebral palsy cases are due to a genetic cause (345,346). Considering all types of cerebral palsy together, the risk of recurrence in sibships is low. However, bilaterally symmetric spastic cerebral palsy (as opposed to hemiplegic or monoplegic cerebral palsy) for which there is no identifiable cause has recurrence risk in sibs of approximately one in eight (345).

McHale et al. (347) identified a locus for autosomal recessive spastic cerebral palsy on chromosome 2q24-25 with a minimum locus interval of approximately 5cM between the markers D2S124 and D2S2284. It is important to note that this locus for autosomal recessive, bilaterally symmetric, spastic cerebral palsy overlaps the SPG13 locus for uncomplicated autosomal dominant HSP (36). It is intriguing to consider that both disorders are due to mutations in the same gene.

Clearly, subjects with some forms of HSP may be misdiagnosed as having spastic diplegic cerebral palsy (235,348–350). It is uncertain, however, whether some or all kindreds with autosomal recessive familial cerebral palsy (351) should be considered forms of autosomal recessive HSP with infantile onset symptoms. It is unknown, for example, whether autosomal recessive familial cerebral palsy linked to chromosome 2q24-25 (347) shares the same pathologic changes as HSP (distal axonal degeneration of corticospinal and dorsal column tracts in the spinal cord).

As a generalization, the primary clinical feature that distinguishes HSP from bilaterally symmetric spastic diplegic cerebral palsy is the *progressive* nature of lower

extremity weakness in HSP (348) (as opposed to *non-progressive* lower extremity spastic weakness in cerebral palsy). Dorsal column impairment, a feature of HSP but not spastic cerebral palsy, is less helpful because vibratory sensation is usually normal in children with HSP.

Nonetheless, there are important exceptions to the generalization that HSP is always a progressive disorder. Specifically, HSP beginning in infancy (or earlier) might not be evident as a progressive disorder. Rather, such children may present with delayed acquisition of walking milestones, lower extremity spastic weakness, and toe-walking in a manner that may not be distinguished from spastic diplegic cerebral palsy. Moreover, for some families with classic features of HSP, the degree of progression may be so insidious and so mild as to be clinically inapparent during childhood. We (350) and others have observed affected subjects with no previous family history of HSP who were diagnosed initially as having spastic diplegic cerebral palsy, only to have this diagnosis changed to autosomal dominant HSP following the appearance of the disorder in their child. In two unrelated families, we documented that this was due to *de novo* SPG3A/atlastin mutation in the proband (235,350). In addition to SPG3A/atlastin mutation, *de novo* mutation in SPG4 has also presented as familial cerebral palsy (352).

**119.3.4.3 Hereditary Motor Sensory Neuropathy (HSMN, also Known as CMT).** Previously, the HSPs were considered categorically distinct from HSMNs. Clinicians can readily distinguish the lower extremity hyperreflexia of HSPs from the lower extremity hypo- or areflexia of the HSMNs. There is growing awareness that these syndromes sometimes overlap. As noted above, many forms of HSP have peripheral neuropathy including forms of HSP that were usually considered “uncomplicated” (e.g., SPG3A and SPG4 HSP). Often, the neuropathy associated with HSP is “axonal” rather than “demyelinating.” This is consistent with the general concept that the lower extremity spasticity and hyperreflexia is due to corticospinal tract and dorsal column axon degeneration; and suggests that axon degeneration (in these forms of HSP) involves both central and peripheral motor and sensory fibers. On the other hand, some forms of HSP, such as X-linked SPG2, due to PLP gene mutation, may have demyelinating or mixed axonal-demyelinating peripheral neuropathy. Indeed, mutations in one gene (BSCL2/Seipin) can manifest as either a predominant peripheral neuropathy syndrome (consistent with a form of type 2, CMT) or a form of HSP associated with peripheral neuropathy (SPG17).

Furthermore, there is increasing awareness that some molecular mechanisms implicated in axon degeneration in HSP are similar to those implicated in axon degeneration in some forms of CMT. For example, whereas mutations in the kinesin heavy chain subunit KIF5A cause SPG10 HSP (353), mutations in a functionally related molecular motor subunit KIF1B- $\beta$  cause a form of CMT

(CMT2A1) (354). Similarly, whereas gap junction A12/connexin 47 gene mutations cause SPG42 HSP (as well as the demyelinating disorder, PMLD) (289), mutations in gap junction beta 1 cause an X-linked form of CMT (CMT1X) (355). In a related manner, FIG4 mutations are implicated in both CMT (CMT4J) (356), and have been identified in both PLS and ALS subjects (357). These examples indicate that the same or overlapping pathogenic mechanisms underlie many forms of these ostensibly clinically disparate syndromes (spastic paraplegias versus peripheral neuropathies).

**119.3.4.4 SPG20/spartin and Colorectal Carcinoma.** Lind et al. (358) reported that SPG20/spartin promoter is hypermethylated in colorectal carcinomas and adenomas, but was not hypermethylated in normal mucosa. They proposed that SPG20/spartin gene methylation status be used as a biomarker of colorectal tumors. In addition to being a biomarker, Lind et al. (358) noted that SPG20/spartin promoter hypermethylation could contribute to neoplasia. Specifically, they observed an association between SPG20/spartin promoter hypermethylation, transcription silencing of the SPG20/spartin gene, and cytokinesis arrest. They noted that cytokinesis arrest could lead to aneuploidy, a mechanism of neoplasia (358).

### 119.3.5 Treatment

There is no effective treatment to prevent, retard, or reverse the process of distal axonal degeneration that underlies HSP. Nonetheless, treatment approaches used for chronic paraplegia from other causes are useful. In particular, spasticity may be reduced with oral or intrathecal Lioresal (baclofen) or oral Dantrolene or Tizanidine and selective injection of botulinum toxin (Botox) (359–361). Oxybutynin is often effective in reducing urinary urgency. Physical therapy is recommended to subjects with HSP to improve range of motion, maintain and increase lower extremity strength, and increase cardiovascular conditioning, which may improve endurance and lessen fatigue. Toe-dragging may be reduced by ankle foot orthotics as well as by devices that provide gait phase-dependent, transcutaneous peroneal nerve stimulation (362).

Regarding placement of intrathecal baclofen pump, it is essential to establish, by one or more trial injections, the extent to which intrathecal baclofen provides improved walking ability. It is emphasized that the important outcome parameter for these trials is not the degree to which lower extremity spasticity is reduced, but rather, the degree to which walking is improved. In general, we have found that reduction of spasticity (e.g., either by oral or intrathecal baclofen) provides greatest functional benefit in HSP subjects who have relatively preserved lower extremity strength. Conversely, in our experience, subjects for whom gait disturbance is attributed to roughly equal contributions of weakness and spasticity benefit less from spasticity-reducing strategies.

**Genetic counseling** in HSP must be individualized for each individual and family. It is important to recognize that genetic penetrance in autosomal dominant HSP is age-dependent and may be as low as 70% (82). Moreover, the age at which symptoms begin and the ultimate degree of disability may vary widely within a given family, between families with the same genetic type of HSP, and between genetic types of HSP. For this reason, it is generally prudent to limit the premise upon which genetic counseling is based on the age-of-symptom onset, phenotypic variability, and genetic penetrance that are present in the patient's family (rather than rely primarily on data from published kindreds describing the same genetic type of HSP). Although the risk of inheriting the HSP disease gene and genetic penetrance can be estimated, it is generally not possible to predict accurately whether HSP symptoms will develop early (e.g., before age 10) or late (e.g., after age 40) or whether HSP will lead to mild or severe disability.

Extreme caution must be exercised when providing genetic counseling to a subject who has all the signs and symptoms of HSP but who has no other similarly affected relatives. While such “apparently sporadic, uncomplicated spastic paraplegia” subjects may have autosomal recessive HSP (and thus low risk of transmitting the disorder to progeny), it is also possible that the disorder is autosomal dominant (with absent family history due to incomplete genetic penetrance, the disorder being due to a *de novo* HSP gene mutation, or mistaken paternity). Five to ten percent of ASSP subjects have been shown to have mutations either in SPG4 or less commonly in SPG3A HSP genes (both of which are autosomal dominant and therefore imply up to 50% risk of disease reoccurrence in each first-degree relative).

**119.3.5.1 Genetic Counseling of Subjects with SPG7 HSP.** A number of subjects with ASSP (both uncomplicated and complicated syndromes) have been shown to have mutations in the SPG7/paraplegin gene (76,297,363). The majority of SPG7/paraplegin mutations discovered in spastic paraplegia subjects are in homozygous or compound heterozygous states. Recently, several groups (76,363,364) have described both “uncomplicated” and “complicated” HSP in subjects who are *heterozygous* for pathogenic SPG7 mutations. In some of the subjects with spastic paraplegia due to *heterozygous* SPG7/paraplegin mutations, muscle biopsies have shown evidence of mitochondrial disturbance including ragged red fibers and cytochrome C oxidase negative muscle fibers. There is incomplete information to determine reliably which SPG7 mutations are pathogenic when homozygous or in compound heterozygous states, which SPG7 mutations are pathogenic when heterozygous, and whether other mutations in regulatory and noncoding SPG7 regions coexist with SPG7 mutations associated with spastic paraplegia when heterozygous. Nonetheless, the finding that at least some SPG7 mutations cause spastic paraplegia when heterozygous has important implications for

genetic counseling. Specifically, subjects with SPG7 HSP who are homozygous for SPG7/paraplegin gene mutation should be informed that unlike “typical” autosomal recessive disorders, their progeny (obligate SPG7 mutation heterozygotes) have some risk of developing some symptoms of HSP which could range from subtle, *forme fruste* to full manifestations of SPG7 HSP.

Some HSP subjects request prenatal diagnosis. For identified HSP genes for which analysis is available (either in commercial laboratories or on a research basis, Table 119-1), prenatal genetic testing can be performed using chorionic villus samples, amniocytes, and blastocyst cells (for preimplantation genetic testing). Prenatal testing for SPG3A, SPG4, and SPG42 HSP (54,188,365) as well as detection of PLP mutations (mutated in SPG2 HSP and PMD) have been reported.

If the HSP locus is known in a given family (but the gene is yet to be identified), it is possible to perform prenatal risk assessment by analyzing fetal inheritance of haplotypes that segregate with “normal” or “HSP affected” alleles in the family (365). Such methods estimate the risk of fetal inheritance of the HSP gene mutation. Genetic counseling must consider not only this information but also estimates of penetrance, range of age-of-symptom onset, and variable disease severity that occur within the particular family.

### 119.3.6 HSP Genes and Encoded Protein Function

A comprehensive catalog of HSP gene mutations and their associated phenotypes and thorough presentation of the emerging molecular biology of HSP proteins is beyond the scope of this chapter. The following section is an overview of HSP protein function.

## 119.4 AUTOSOMAL DOMINANT HSP

### 119.4.1 SPG3A/atlastin (17)

SPG3A gene mutations are the most frequent cause of childhood onset, dominantly inherited HSP (308,366,367). Several dozen SPG3A/atlastin mutations have been identified. Often, mutations are “private,” being uniquely present in the families in which they are identified. The existence of SPG3A/atlastin mutation that disrupts a conserved GTPase motif (R271Q) indicates the likelihood that atlastin is a functional GTPase (368). SPG3A/atlastin mutations appear to be pathogenic through haploinsufficiency. This is supported by observations of SPG3A/atlastin insertion mutation that leads to a stop codon and premature protein truncation (369), and by the occurrence of gait impairment and neuropathologic changes in mice bearing targeted mutation of SPG3A/atlastin gene (J. K. Fink et al. unpublished observation).

SPG3A/atlastin is homologous to guanylate-binding protein 1 (GBP1), a member of the dynamin family of

large GTPases (17). Dynamins play essential roles in a wide variety of vesicle trafficking events during formation of clathrin-coated vesicles from the plasma membrane, receptor-mediated endocytosis, and endosome trafficking to the *trans*-Golgi network (370,371). Consistent with this role, Zhu et al. (372) showed that atlastin was present in *cis*-Golgi membranes of cortical motor neurons.

Atlastin binds to itself (homodimer) in a nucleotide-dependent manner (373). Luan et al. (374) reported that atlastin interacts *in vitro* with HPK/GCK-like kinase (HGK), a protein kinase in the c-Jun N-terminal kinase (JNK) pathway. JNK pathway signaling leads to diverse effects including differentiation and apoptosis.

Recently, atlastin has been demonstrated to interact *in vitro* with three other HSP proteins, SPG4/spastin, SPG6/NIPA1, and SPG31/REEP1, and to play a critical role in development of endoplasmic reticulum morphology, particularly in the formation of three-way tubular junctions (375–382).

Endoplasmic reticulum stress cascade (e.g., due to misfolded proteins) is a widely recognized factor in many neurodegenerative disorders (e.g., those due to polyglutamine repeat expansions) including a number of forms of HSP (notably, SPG8/Strumpellin and SPG17/BSC12 (seipin)). Demonstration that atlastin, spastin, REEP1, and NIPA1 interact and that atlastin, spastin, and REEP1 help determine endoplasmic reticulum morphology represent seminal advances in our knowledge of the molecular mechanisms of four types of HSP (SPG3A, SPG4, SPG6, and SPG31). Moreover, these discoveries emphasize the importance of endoplasmic reticulum function and morphology in the maintenance of axon structure in health and disease.

### 119.4.2 SPG4/Spastin Gene (383)

SPG4 is the single most common type of autosomal dominant HSP, representing ~40% of such patients. More than 300 SPG4/spastin mutations have been identified in HSP patients. These mutations have been of all types (missense, nonsense, deletion, insertion, whole exon deletion, and aberrant splicing) except tandem repeat expansions. Whereas nonsense, frameshift, and splice site mutations are distributed throughout the gene (except exon 4 which is not expressed in the central nervous system), missense mutations are located predominantly in spastin’s AAA domain (“ATPase associated with diverse cellular activities”) (383). Many SPG4/spastin mutations are predicted to cause loss of spastin function. Both haploinsufficiency and dominant gain function mechanisms have been proposed for spastin mutation pathogenicity (384).

Spastin is expressed widely; although within the spinal cord, spastin is present only in neurons and not glia (18). Spastin’s intracellular distribution has been the subject of controversy as both nuclear (18) and cytoplasmic (385–388) localizations have been reported using

various techniques. There is evidence that spastin has dual nuclear and cytoplasmic localization owing to alternate translation initiation that results in large (68 kDa) and small (60 kDa) spastin isoforms (389). Whereas both isoforms are imported into the nucleus, the larger (68 kDa) isoform contains two nuclear export signals and is efficiently exported to the cytoplasm. The larger (68 kDa) spastin isoform is more abundant in brain and the spinal cord compared to other tissues.

Reid et al. (390) showed that spastin interacts with CHMP1B, a protein associated with the endosomal sorting complex required for transport (ESCRT)-III complex. This suggests that spastin participates in intracellular membrane traffic events.

Azim et al. (391) showed that spastin interacts with tubulin in vitro (391). Studies of transfected cells expressing wild-type and mutant spastin suggest that HSP-specific *SPG4* mutations disturb spastin's interaction with microtubules (385–387). Spastin's interaction with microtubules appears to be mediated through spastin's N-terminal region and regulated through the ATPase activity of the AAA domain (385). Compared to wild-type spastin, studies in transfected cells showed that mutant spastin had aberrant cytoplasmic localization and diminished promotion of microtubule disassembly (386,387). Transfection studies also provide evidence that mutant spastin expression leads to altered distribution of organelles (386) including mitochondria and peroxisomes. McDermott et al. (386) concluded that mutant spastin interferes with anterograde transport of these organelles.

A portion of spastin shares homology with katanin, a microtubule severing enzyme (392). There is in vitro and in vivo evidence that spastin has microtubule severing properties (19,393,394). For example, overexpression of *Drosophila*'s spastin homolog (*Dspastin*) in *Drosophila* S2 cells produced nearly complete absence of cytoplasmic microtubules (393). Trotta et al. (395) used RNA interference to examine loss of spastin function in *Drosophila*. They observed that loss of spastin resulted in aberrant stabilization of microtubule cytoskeleton in neurons and defects in synaptic growth and neurotransmission.

Axonal cytoskeletal stability and axonal transport depend to a large extent on dynamic microtubule “remodeling” (assembly, disassembly, and movement of short microtubules into new patterns of organization (396)). The ability of neurons to mobilize microtubules appears to depend on microtubule severing enzymes, such as spastin and katanin, which cleave microtubules into shorter fragments that can be moved to new locations and subsequently elongated (396). Spastin mutations in *SPG4* HSP appear to reduce microtubule severing and thus compromise neuronal cytoskeletal remodeling and possibly interfere with axonal transport.

As noted above, spastin interacts with atlastin (378,379,381). Further, in addition to tubulin binding and microtubule severing properties, Spastin has been

shown to participate with atlastin and REEP1 in the coordination of microtubule interactions with tubular endoplasmic reticulum (379).

### 119.4.3 SPG6/NIPA1

SPG6 HSP is a prototypical example of slowly progressive, uncomplicated HSP that usually begins in adolescence or adulthood (see reviews by Fink et al. (24) and Fink and Hedera (62)). It is notable that only 4 *SPG6*/*NIPA1* amino acid substitutions have been identified among five unrelated SPG6 families. Rainier et al. (26) reported T45R mutation in an Iraqi family and an Irish family. G106R mutation has been reported in a British family, a Brazilian family, and in two unrelated Chinese families (23,397,398). It is interesting that in the case of the two Chinese SPG6 families, the G106R mutations arose by two different mutations in each family involving the same nucleotide: one family had mutation at nucleotide 316 G→C and one family had mutation at the same nucleotide but with 316 G→A. Each change led to the same amino acid substitution (G106R). These observations suggest that this *SPG6*/*NIPA1* region may be a mutational “hot spot” (23).

*NIPA1* is expressed predominantly in the central nervous system. The presence of nine alternating hydrophobic–hydrophilic domains suggests that *NIPA1* encodes a membrane protein. *NIPA1* mutation T45R appears to act through a “dominant negative” gain of function. This prediction is based on the observation that subjects who are missing one *NIPA1* gene entirely (e.g., subjects with Prader–Willi and Angelman syndromes who have deletions involving this region of chromosome 15q) do not develop HSP (26,399).

Recent insights into *NIPA1* function are emerging. There is evidence, for example, that *NIPA1* binds to bone morphogenic protein 2 (BMP-II) receptor to inhibit BMP signaling (400,401) (BMP signaling has also been shown to be inhibited by *SPG4*/spastin and *SPG20*/spartin (400)). In addition, Goytain et al. (376) showed that *NIPA1* transcription is enhanced by low extracellular Mg<sup>++</sup>, and that *NIPA1* expression causes inwardly direct Mg<sup>++</sup> conductance in vitro. Finally, as discussed above, *NIPA1* has been shown to interact with *SPG3A*/atlastin, which has been recently implicated in determining endoplasmic reticulum morphology. *NIPA1* accumulation in a *Caenorhabditis elegans* model was associated with evidence of endoplasmic reticulum stress response (163).

### 119.4.4 SPG8/KIAA0196/Strumpellin

Following discovery of the *SPG8* locus on chromosome 8q23–q24 (27), Valdmann et al. (29) identified KIAA0196 (“Strumpellin”) gene mutations in affected subjects in this kindred. To date, *SPG8*/*KIAA0196*/Strumpellin mutations have been reported in four unrelated families (27,29,402,403).

SPG8/KIAA0196/Strumpellin mutations may be pathogenic through protein aggregation. Clemen et al. (404) showed that Strumpellin binds to valosin-containing protein (VCP). VCP-positive inclusions occur in a wide variety of neurodegenerative disorders including Parkinson's disease, Lewy body disease, Huntington's disease, ALS, and SCA type III (Machado–Joseph disease) (405). Through induction of endoplasmic reticulum stress response, protein accumulation is increasingly recognized as a common pathologic mechanism in a wide variety of degenerative neurologic disorders (reviewed in (406)).

Ropers et al. (407) showed that Strumpellin is present in a protein complex that includes WASH, and which localizes to endosomal subdomains and regulates endocytic vesicle severing. WASH's action on endocytic vesicles depends on Arp/23 (407), an important factor in nucleation of actin from monomers (408,409). By extrapolation, this raises the possibility that Strumpellin mutations could be pathogenic by misregulation of actin dynamics on endosomes.

#### 119.4.5 Kinesin Heavy Chain (KIF5A) Mutations Cause SPG10 HSP

KIF5A is a molecular motor that participates in the intracellular movement of organelles and macromolecules. KIF5A gene mutation was recently identified in affected HSP subjects linked to the SPG10 locus (353). Subjects with KIF5A mutation exhibited either uncomplicated HSP, or HSP associated with distal muscle atrophy (353). Finding *KIF5A* mutations in SPG10 HSP suggests that degeneration of distal axons in this and possibly of other forms of HSP is related to disturbance of axonal transport (410).

It is noteworthy that mutations in another molecular motor component, kinesin light chain, cause axon degeneration limited to the *peripheral nervous system* (CMT type 2A1) (354). Together with the finding that dynactin mutations cause motor neuron disease (411), there is increasing evidence that abnormalities in axonal transport cause degeneration of both central nervous system axons (leading to an HSP phenotype), and peripheral axons (leading to a phenotype of peripheral neuropathy and lower motor neuron disease).

Wang and Brown (412) examined the consequences of SPG10/KIF5A mutation N256S on neurofilament transport in vitro. Expression of this mutation in cultured mouse cortical neurons decreased both anterograde and retrograde neurofilament transport flux by decreasing the frequency of anterograde and retrograde movements. Ebbing et al. (413) studied four different KIF5A mutations and observed that some mutations reduced KIF5A's affinity for microtubules, other mutations affected KIF5A's gliding velocity, and some mutations affected both microtubule binding and gliding velocity.

*Mutation in heat shock protein 60 (also known as chaperonin 60)*, a mitochondrial protein, cause SPG13 ADHSP, an autosomal dominant form of uncomplicated HSP mapped (37). The mechanism by which Hsp60 mutations cause HSP is not clear.

Hansen et al. (414) examined lymphoblastoid cell lines and fibroblasts from a subject with Hsp60 mutation p.Val98Ile. They studied mitochondrial membrane potential, cell viability, and sensitivity to oxidative stress and found no differences from control cells. Interestingly, they observed decreases in mitochondrial protein quality control proteases, Lon and ClpP, and proposed that this may be an adaptive mechanism in response to increased refolding attempts of Hsp60 substrate proteins. It is intriguing that paraplegin, mutations in which cause SPG7 HSP, is also a mitochondrial protein that may play a role in mitochondrial protein quality control.

#### 119.4.6 BSCL2 Mutations Cause Dominantly Inherited HSP Associated with Distal Wasting (Silver Syndrome) and Distal Hereditary Motor Neuropathy (41)

The BSCL2 gene encodes seipin, an integral endoplasmic reticulum membrane (ER) protein. Null mutations in BSCL2 cause congenital lipodystrophy REF. BSCL2 mutations (N88S and S90L) in Silver syndrome affect glycosylation of seipin and result in aggregate formation, leading to neurodegeneration (41,415). In this regard, seipinopathies are regarded as important examples of disorders due to abnormal protein conformation in which activation of the endoplasmic stress response evokes a molecular cascade resulting in neurodegeneration (318,415,416).

#### 119.4.7 SPG31/receptor Expression Enhancing Protein 1 (REEP1)

Beetz et al. (44) found 15 REEP1 mutations (in 16 subjects) among 535 unrelated individuals including subjects with HSP and subjects with apparently sporadic spastic paraplegia. Most REEP1 mutations are considered to be pathogenic through haploinsufficiency (44). Park et al. (379) showed that REEP1 is structurally related to the DP1/Yop1 p family of endoplasmic reticulum-shaping proteins that are required for endoplasmic reticulum network formation. They showed that REEP1 forms complexes with atlastin and spastin within endoplasmic reticulum; and furthermore that REEP1 binds to microtubules and promotes alignment of endoplasmic reticulum along microtubules in vitro (379).

#### 119.4.8 SPG33/ZFYVE (Protrudin)

ZFYVE27 encodes a protein with several transmembrane domains, including a Rab11-binding domain and a lipid-binding, FYVE finger domain REF. ZFYVE27/protrudin

has a role in Rab11-mediated membrane trafficking and promotes neurite outgrowth (74).

Mannan et al. (47) performed yeast two-hybrid analysis to identify spastin-interacting proteins and identified ZFYVE27 and four additional proteins. REF In their analysis of 43 German HSP families, they identified an autosomal dominant kindred in which ZFYVE27 mutation p.G191V was present in two affected siblings, absent in an unaffected siblings, and absent in 210 control chromosomes. Subsequently, Martignoni et al. (417) reported that pG191V was a benign polymorphism which, in their in vitro studies of neurite extension and Rab11 binding, functioned similar to wild-type ZFYVE27. Pending identification of additional HSP families with ZFYVE27 mutation and clear demonstration of mutation pathogenicity, assignment of ZFYVE27 as a cause of HSP is controversial.

#### 119.4.9 SPG42/SLC33A1

Genetic linkage analysis and positional candidate gene analysis led to identification of SLC33A1 gene mutation (resulting in p.S113R) in one Chinese, autosomal dominant HSP kindred (53). Analysis of 220 European, autosomal dominant HSP families did not identify SLC33A1 mutation (55). RNAi-mediated knockdown of SLC33A1 resulted in an abnormal tail phenotype in Zebrafish (53). This abnormal phenotype could be rescued by wild-type but not mutant human SLC33A1 mRNA (53).

SLC33A1 encodes an acetyl CoA transporter that moves acetyl-CoA into the Golgi apparatus where it may be transferred to sialyl residues of gangliosides and glycoproteins (see (53) for discussion and references).

### 119.5 AUTOSOMAL RECESSIVE HSP GENES

#### 119.5.1 SPG5/CYP7B1

Hentati et al. (1994) identified the SPG5 locus in five Tunisian families with uncomplicated HSP. Wilkinson et al. and Muglia et al. refined this locus and Tsaousidou et al. (418) identified mutations in the cytochrome P450-7B1 (CYP7B1) gene in five SPG5-linked families. Studies by Biancheri et al. (419) and Goizet et al. indicate that CYP7B1 mutations are a frequent cause of autosomal recessive HSP occurring in 7.3–8% of subjects as well as ~3% among subjects with apparently sporadic spastic paraplegia.

Tsaousidou et al. (418) point out that CYP7B1 provides the primary metabolic route for cholesterol derivatives dehydroepiandrosterone (DHEA) and related hydroxysteroids *via* 7 $\alpha$ -hydroxylation, and that in the liver, CYP7B1 provides an alternative route for cholesterol metabolism. Discovery that CYP7B1 mutations cause HSP represents the first example that altered cholesterol metabolism can result in motor neuron disease.

It is noteworthy that altered cholesterol metabolism from mutations in another cytochrome p450 protein (CYP27A) results in a neurodegenerative disorder (cerebrotendinous xanthomatosis) whose clinical presentation (including juvenile cataracts, neuropathy, spastic paraparesis, ataxia, and white matter abnormalities on MRI) may overlap some forms of complicated HSP.

#### 119.5.2 SPG7/Paraplegin

Casari et al. (254) discovered the paraplegin gene at the SPG7 locus and found disease-specific paraplegin gene mutations in affected subjects from two unrelated autosomal recessive HSP kindreds. Like spastin, paraplegin contains an AAA motif. Paraplegin is homologous to several yeast mitochondrial metalloproteases (AFG3, RCA1, and YME1), which have both proteolytic and chaperone activities (254,420). Casari et al. (254) demonstrated that paraplegin is localized exclusively to mitochondria and that some affected HSP affected subjects with paraplegin gene mutations have histologic evidence (ragged red fibers) and histochemical evidence (no reaction to cytochrome C oxidase) in skeletal muscle biopsy.

Atorino et al. (421) showed that paraplegin interacts with a homologous protein AFG3L2 to form a complex in the inner mitochondrial membrane. This paraplegin/AFG3L2 complex is reduced in fibroblasts from SPG7 HSP subjects who have homozygous paraplegin mutations. Such fibroblasts show reduced mitochondrial complex I activity and an increased sensitivity to oxidative stress, features that can be rescued by expression of wild-type paraplegin. Nolden et al. (422) studied the AAA-protease-dependent processing of the mitochondrial ribosomal protein MrpL32 in mice bearing targeted paraplegin gene mutation. They observed that maturation of MrpL32 and mitochondrial protein synthesis was impaired in paraplegin-deficient mice. This suggests that paraplegin mutations in SPG7 HSP may be pathogenic by impairing mitochondrial protein synthesis.

As noted above, paraplegin complexes with AFGL2 to form a heteromeric mitochondrial complex that contributes to mitochondrial protein quality control and provides chaperone-like activity on the respiratory chain complexes (423). While SPG7/paraplegin mutations cause corticospinal tract degeneration (often associated with cerebellar and peripheral nerve involvement), mutations in AFGL2 cause mitochondria-dependent, Purkinje cell degeneration ascertained clinically as SCA type 28 (SCA28). In mouse models, the SPG7/paraplegin knockout phenotype is made more severe in the presence of AFGL2 knockout (424). This raises the possibility that variation in AFGL2 function (such as through genetic polymorphism) may modify the SPG7 HSP phenotype (and conversely, that SPG7/paraplegin functional variation may modify the phenotype of SCA 28).

SPG11/*Spatacsin* function is not known. Spatacsin does not share significant sequence similarity with other

proteins (251). Nonetheless, spatacsin is a component of a protein complex that includes two other HSP proteins, SPG15/ZFYVE26 and SPG48/KIAA0415 (316), suggesting that these forms of HSP may share similar molecular pathogenesis.

*SPG15/Spastizin (ZFYVE26)* is one of more than 30 mammalian proteins that share a highly conserved, zinc-finger-binding domain characterized by eight conserved cysteine residues (summarized in (259)). FYVE-domain proteins have diverse functions including membrane trafficking, signal transduction, regulating the cytoskeleton, and serving as phosphatidylinositol 3-phosphate (PtdIns3P) phosphatases (reviewed in (425)). Spastizin colocalizes with endoplasmic reticulum and endosome markers, suggesting that it may play a role in endosomal trafficking (259). It is notable that ZFYVE26/Spastizin was demonstrated to be a component of a protein complex that includes two other HSP proteins, SPG11/spatacsin and SPG48/KIAA0415 (316). Moreover, there is evidence that another FYVE-containing protein (ZFYVE27) interacts with SPG4/spastin and may be implicated in SPG33 HSP REF. These observations suggest that these forms of HSP (SPG4, SPG11, SPG15, SPG48, and possibly SPG33) may share common molecular pathogenesis, and that disturbance of membrane trafficking may be an important mechanism (426).

### 119.5.3 SPG20/Spartin (266)

This gene is designated “Spartin” (SPastin-related Autosomal Recessive Troyer protein) because the amino-terminal region is similar to that of spastin’s mutations which cause SPG4 HSP. Spartin’s function is unclear and it is intracellular and may be complex. Bakowska et al. (427) observed that spartin was distributed to both cytosolic and membrane fractions. Whereas Lu et al. (428) observed Spartin localization to mitochondria, Robay et al. (429) noted that spartin’s location (in SH-SY5Y cells) changed with differentiation. In undifferentiated cells, spartin displayed diffuse nuclear and cytosolic localization. Following differentiation into neuroblasts, spartin colocalized with synaptic vesicle marker synaptotagmin and was enriched in synaptic-like structures. Robay et al. (429) showed that following epidermal growth factor (EGF) stimulation, spartin translocated from cytoplasm to the plasma membrane, and suggested that spartin may be involved in the intracellular trafficking of EGF receptor. Eastman et al. (430) showed that spartin associates with surface lipid droplets and can regulate their size and number. Milewska et al. (431) investigated spartin-interacting proteins, confirmed that spartin interacted with GRP78, GRP75, ubiquitin, and the E3 ubiquitin-protein ligases, AIP4/Itch and AIP5/WWP1, and established that spartin interacted with the nucleolar protein nucleolin. Their studies suggested that spartin is a multifunctional protein with potential functions in protein folding and protein turnover both in mitochondria and in endoplasmic

reticulum. The observation that spartin interacts with Eps 15, a protein known to be involved in endocytosis and the control of cell proliferation, suggests that spartin may be involved in endocytosis, vesicle trafficking, or mitogenic activity (427).

Recently, Lind et al. (358) reported that SPG20/spartin promoter is hypermethylated in colorectal carcinomas and adenomas, that hypermethylated spartin promoter leads to transcription silencing of the SPG20/spartin gene, and that reduced SPG20/spartin is associated with cytokinesis arrest. Cytokinesis’ arrest may lead to aneuploidy, a mechanism of neoplasia (358). The authors propose that SPG20/spartin gene methylation status be used as a biomarker of colorectal tumors.

*SPG21/Maspardin* mutations cause “Mast syndrome,” an autosomal recessive complicated form of HSP associated with slowly progressive ataxia and extrapyramidal signs, thin corpus callosum, white matter abnormalities, and dysphagia (162). The disorder progresses insidiously beginning in adolescence or adulthood and leads to akinetic mutism in the most severely affected subjects. Simpson et al. (162) mapped the disorder to a locus on chromosome 15q22.31 and identified disease-specific mutations in a novel gene (Maspardin) within this locus. Maspardin’s function is unclear, although there is evidence that it may function in endosomal trafficking. Maspardin appears to be a cytosolic protein partitioned between the cytosol and vesicles of the endosomal/trans-Golgi network (162,432). Protein homology comparisons suggest that maspardin is related to an  $\alpha/\beta$  hydrolase superfamily of diverse enzymes and may be similar to a noncatalytic  $\alpha/\beta$  hydrolase protein “N-myc downstream regulated” (NDRG1). Mutations in NDRG1 cause autosomal recessive peripheral neuropathy with early axonal involvement (162). Hanna et al. (432) showed that maspardin interacts with aldehyde dehydrogenase ALDH16A1. There are at least 19 other human aldehyde dehydrogenases. Although the specific functions of ALDH16A1 are not known (432), it is relevant that mutations in another aldehyde dehydrogenase ALDH3A cause spastic paraplegia, mental retardation, and congenital ichthyosis (Sjögren–Larsson syndrome) (432) (reviewed in (262)).

### 119.5.4 SPG35/Fatty Acid 2-Hydroxylase (FA2H)

Dick et al. (160) identified mutations in the fatty acid 2-hydroxylase (FA2H) gene in an Omani and a Pakistani family with complicated spastic paraplegia. Affected subjects had childhood onset of spastic paraplegia, progressive dysarthria, dementia, seizures, and variable thin corpus callosum, and brain white matter abnormalities.

FA2H is an important factor in myelin formation and is an important factor in determining myelin lipid content. FA2H is present in oligodendrocytes where it catalyzes the 2-hydroxylation of myelin galactolipids,

galactosylceramine, and sulfatide (160,433). Edvardson et al. (433) reported FA2H mutations in subjects with childhood-onset spasticity, dystonia, cognitive dysfunction, and periventricular white matter disease. The variable phenotype associated with FA2H mutation was expanded by Kruer et al. (161) to include childhood onset, spastic quadriparesis, ataxia, and dystonia and episodic neurological decline, and importantly, the appearance of iron accumulation in brain MRI.

### 119.5.5 SPG39/Neuropathy Target Esterase

Rainier et al. (274) analyzed two autosomal recessive kindreds with childhood-onset spastic paraplegia associated with progressive muscle atrophy in distal upper and lower extremities. The phenotype in these families conformed to that of Troyer syndrome. Homozygosity mapping in one consanguineous kindred suggested linkage to a locus on chromosome 19p13 that contained the NTE gene. NTE was considered a high priority candidate gene because of its involvement in the pathogenesis of OP-induced delayed neuropathy (OPIDN) syndromes in humans and laboratory animals (434–439). OPIDN syndromes include axon degeneration particularly involving long, central, and peripheral fibers, findings that were present in the HSP family with NTE mutation. Rainier et al. (274) showed that affected subjects in the consanguineous kindred were homozygous for M1012 V mutation that disrupted an interspecies conserved residue in NTE's esterase domain. Affected subjects in the nonconsanguineous kindred were compound heterozygotes for two NTE mutations: one allele had 2826A > G mutation which caused substitution of an interspecies conserved residue R890H in NTE's catalytic domain, the other allele had a four base pair insertion (NTE mRNA position 3104) that caused protein truncation after residue 1020. Observations of NTE mutation as the cause of corticospinal and peripheral motor axon degeneration in SPG39 HSP indicates the importance of the NTE pathway in maintaining axon integrity, and raises the possibility that NTE pathway disturbances (and possibly organophosphate exposure) could contribute to other motor neuron disorders including ALS.

NTE may play a role in membrane lipid homeostasis. NTE is a widely expressed, endoplasmic reticulum membrane-associated phospholipase A1 that deacylates intracellular membrane phosphatidylcholine to glycerophosphocholine (440–443). Phosphatidylcholine is a major component of animal cell membranes. High concentrations of lysophosphatidylcholine (LPC) are cytotoxic (444). Recent studies (445) suggest that NTE is involved in LPC homeostasis, protects cells from LPC cytotoxicity (445), and affects membrane fluidity. NTE's *Drosophila* homolog SWS binds to the C3 catalytic subunit of PKA, inhibit its activity, and tethers it to endoplasmic reticulum membranes (446). From their observations, Bettencourt da Cruz et al. (446) propose

that “SWS acts as a noncanonical subunit for PKA-C3, whereby the complex formation regulates the localization and kinase activity of PKA-C3, and that disruption of this regulation can induce neurodegeneration.”

### 119.5.6 SPG44/GJA12/GJC2 (Connexin 47, Cx47) (290)

Specialized channels (“gap junctions”) between cells allow selective movement of ions and metabolites between adjacent intracellular compartments. This is an important factor in the molecular and electrical functional integration of cells and tissues (see review by (288)). To a large extent, gap junctions are formed by connexin proteins (288). For review of the gap junction mutations in myelinating cells, see (447).

Mutations in the gap junction protein alpha 12 [GJA12/GJC2] gene (which encodes connexin 47) cause the autosomal recessive disorder, “PMLD” (289,448), an early-onset dysmyelinating disorder associated with nystagmus, psychomotor delay, progressive spasticity, ataxia. GJA12/GJC2 gene mutations also cause a relatively milder phenotype (designated SPG44) that begins in the first and second decades and is characterized by cognitive impairment, slowly progressive, spastic paraplegia, dysarthria, and upper extremity involvement. As with PMD and PMLD, MRI and MR spectroscopy imaging in SPG44 HSP is consistent with a hypomyelinating leukoencephalopathy (290).

In addition to GJA12/GJC2 mutations, Wang et al. (449) recently reported that mutations in the AIMP1 gene (which encodes ARS-interacting multifunctional protein 1) also cause autosomal recessive, infantile onset, PMLD disease. Although a late-onset, more mild phenotype (compatible with complicated HSP) has not been described, the examples that early-onset dysmyelinating disorders, PMD and PMLD, are allelic with later-onset, more slowly progressive spastic paraplegias (SPG2 and SPG44 HSP), make it likely that some AIMP1 gene mutations also cause later-onset, more slowly progressive disease consistent with a complicated form of HSP.

SPG48/KIAA0415 encodes a putative helicase involved in double-strand DNA repair (316). KIAA0415 interacts with SPG11/Spatacsin and SPG15/ZFYVE27 suggesting that common molecular mechanisms may be involved in these forms of HSP (316).

*Epsilon subunit of the cytosolic chaperonin-containing t-complex peptide-1 (Cct5) gene* causes mutilating sensory neuropathy associated with progressive spastic paraplegia (119,450). An “SPG” designation has not been made. As a component of two chaperone systems, Cct5 contributes to the protein folding and assembly of a wide variety of cytosolic proteins including actin and tubulin (119). This suggests that Cct5 mutations could be pathogenic through protein misfolding [a mechanism invoked for SPG8/Strumpellin, SPG13/Chaperonin 60,

and SPG17/BSCL2 (Seipin)] and/or through cytoskeletal abnormalities including axon transport disturbance.

## 119.6 X-LINKED HSP GENES

*Neuronal cell adhesion molecule L1 gene (L1CAM) mutations* cause several neurologic disorders including X-linked hydrocephalus, MASA syndrome, and complicated spastic paraplegia (451,452). Although some of these syndromes correlate with specific L1CAM mutations (e.g., see (453)), modifying factors are implicated because X-linked hydrocephalus, MASA, and X-linked spastic paraplegia have occurred in the same kindred in which affected individuals had the same L1CAM mutation (280).

L1CAM is an integral membrane glycoprotein cell adhesion molecule in the immunoglobulin superfamily. L1CAM is found primarily in the nervous system. Cell adhesion molecules mediate cell-to-cell and cell-to-matrix attachment. For example, L1 interacts with integrin to regulate attachment to proteins in the extracellular matrix (454). L1CAM functions include guidance of neurite outgrowth during development, neuronal cell migration, and neuronal cell survival (451,454,455). Mice bearing targeted L1CAM gene disruption (456) exhibited weak hind limbs and reduced size of corticospinal tracts. It is interesting that bone morphogenic protein (BMP) increases expression of L1CAM (457) in light of observations that SPG4/spastin, SPG6/NIPA1, and SPG20/Spartin appear to inhibit BMP signaling (400,401).

### 119.6.1 PLP Gene Mutations Cause Both PMD and X-Linked, Complicated SPG2 HSP (144,458)

PLP gene mutations cause PMD which is characterized by severe dysmyelination (such as in jimpy mice) (459,460). In stark contrast to the childhood leukodystrophy PMD, SPG2 HSP patients develop normally and experience slowly progressive spastic gait beginning in childhood and adolescence. SPG2 is considered a complicated form of HSP because affected subjects may have peripheral neuropathy and abnormal appearing white matter on brain MRI scans indicative of abnormal CNS myelin. PLP is an integral myelin protein expressed in oligodendroglia (which express an oligodendroglial-specific splice variant of PLP known as DM20 (461)), and Schwann cells but not in neurons. Murine models of SPG2 HSP exhibit either demyelination or axonal degeneration depending on the nature of the PLP mutation (discussed below). Axon degeneration in SPG2 HSP thus appears to be secondary to an intrinsic disturbance in oligodendroglial cells that disturbs axon–glial interaction (291), rather than from an intrinsic abnormality within neurons per se.

*SPG22/Monocarboxylate transport 8 (MCT8) gene* mutations cause AHD syndrome, characterized by neck

muscle hypotonia in infancy, mental retardation, dysarthria, ataxia, spastic paraplegia, and abnormal facies (462). MCT8 encodes a thyroid transporter, essential for triiodothyronine (thyroid hormone T3) uptake into neurons, where it is transported to the nucleus, interacts with nuclear receptors, and then degraded. MCT8 mutations block T3 uptake which prevents both its interaction with its intracellular receptors (therefore preventing its modulation of expression of a variety of genes), as well as its intracellular degradation (therefore resulting in elevated serum triiodothyronine (T3) levels) (462).

*Mitochondrial ATP6 (mATP6) gene mutations* cause a variety of clinical syndromes depending in part on heteroplasmy (relative abundance of mutant and normal mitochondria in each tissue). Genetic background, including both nuclear and mitochondrial genes (e.g., mitochondrial haplogroup) also appears to contribute to phenotypic variation. MATP6-associated syndromes include neuropathy ataxia and retinitis pigmentosa, neonatal Leigh syndrome, and recently, a syndrome of adult-onset, progressive, mild to severe spastic paraplegia variably associated with axonal neuropathy, late-onset dementia, and cardiomyopathy (212).

Verny et al. (212) showed that mATP6 gene mutation discovered in their spastic paraplegia subjects (m.9176 T > C) caused severe reduction in ATP synthesis. The finding that mATP6 mutations can present as progressive spastic paraplegia underscores observations that at least two other HSP genes encode mitochondrial proteins [SPG7/paraplegin and SPG13/chaperonin 60/heat shock protein, (37,155)]. In addition, discovery of mATP6 mutation-related progressive (complicated) spastic paraplegia is the first example of maternally inherited HSP.

## 119.7 EMERGING CONCEPTS OF HSP PATHOGENESIS

Analysis of the 22 HSP genes discovered to date indicates that HSP syndromes result from a variety of primary molecular abnormalities (181,410,463). Rather than reflecting a common biochemical disturbance, phenotypic similarity between different types of HSP appears to reflect the limited repertoire of neurologic symptoms that are caused by relatively selective degeneration of long CNS axons, as well as the limited sensitivity of neurodiagnostic studies to discriminate between these disorders.

Analysis of HSP genes discovered thus far suggests the following primary biochemical abnormalities in different types of HSP: (1) axonal transport abnormality; (2) disturbance in ER morphology; (3) mitochondrial abnormality; (4) primary myelin abnormality; (5) abnormal protein conformation leading to ER-stress response; and (6) disturbance in corticospinal tract development. Whether these biochemical abnormalities ultimately converge into one or more common biochemical pathways remains to be determined.

Axonal transport disturbance has long been suspected as an underlying molecular process in HSP in view of the relatively selective degeneration of the longest CNS axons, the fact that degeneration is maximal at the distal ends of these axons, and the importance of axon transport in axonal biology in general and long axons in particular (410,464). The clearest example of axonal transport disturbance in HSP is autosomal dominant SPG10 HSP due to kinesin heavy chain (KIF5A) mutation. KIF5A is a molecular motor involved in anterograde axonal transport of organelles and macromolecules including neurofilaments (465). SPG4 HSP may also be an example of HSP due to axonal transport disturbance. *SPG4*/spastin interacts with microtubules and appears to be involved in microtubule severing (19,22,179,300,364,386,466–469). Kasher et al. (470), using time-lapse microscopy, showed that neurons from spastin mutant mice had abnormal anterograde and retrograde transport (including the transport of mitochondria).

Two types of HSP, SPG3A and SPG17, may be due to Golgi abnormalities. Although the functions of these *SPG3A*/atlastin and *SPG17*/spartin are unknown, both atlastin and spartin have been shown to be localized to Golgi (372,471).

Three HSP genes encode integral mitochondrial proteins: chaperonin 60/heat shock protein 60, mutations in which cause autosomal dominant uncomplicated SPG13 HSP (37); and paraplegin, mutations in which cause autosomal recessive SPG7 HSP; and mitochondrial ATP6 (254,421,472,473). Some, but not all, SPG7 HSP subjects have morphologic and histochemical abnormalities of mitochondria in skeletal muscle biopsy (155). These findings indicate that mitochondrial disturbance underlies at least two types of HSP, an observation consistent with emerging evidence of mitochondrial abnormalities in other degenerative neurologic disorders (474,475).

Three HSP protein, *SPG3A*/Atlastin, *SPG4*/spastin, and REEP1, have been implicated in determining ER maturation of ER into a meshwork of interconnected tubules. It is noted that mitochondrial abnormality may involve specific oxidative phosphorylation impairment, mitochondrial protein quality control, or both.

Discovery that mutations in PLP, an intrinsic myelin protein, and GJA12/connexin 47 cause either a childhood-onset leukodystrophy (PMD and PLMD, respectively) or slowly progressive spastic paraplegia (SPG2 and SPG44) provides important insights into axonal biology and the causes of HSP. This underscores the concept that axon degeneration in at least two forms of HSP arises from glial abnormality rather than intrinsic neuron abnormality.

Several forms of HSP appear to be *developmental* disturbance rather than progressive neurodegeneration. These include AHD syndrome (SPG22) and SPG1 HSP, both of which are congenital. In the case of SPG1 HSP, the implicated gene (L1CAM) is involved in neuronal migration and corticospinal tract development. AHD

syndrome (SPG22) is a form of congenital insensitivity to thyroid hormone due to mutations in the thyroid transporter MCT8, essential for T3 uptake into neurons.

Abnormal protein accumulation and induction of ER stress cascade have been implicated in many forms of HSP including SPG6, SPG8 (163), and SPG17. In particular, SPG17 (due to BSCL2/seipin gene abnormalities) (318,415,416), SPG8 (due to Strumpell's mutation) (404), and "mutilating sensory neuropathy with spastic paraplegia" due to *CcT5* mutation (119) are important examples of spastic paraplegia protein misfolding and protein accumulation.

## 119.8 ANIMAL MODELS OF HSP

There are numerous animal models of various types HSP (476) including mouse, rat, *Drosophila*, zebrafish, *C. elegans*, and cattle (summarized in Table 119-6). In general, these models have proven useful in evaluating the functional significance of specific HSP mutations; and in exploring the molecular pathogenesis of various forms of HSP. As a generalization, mouse models of HSP (either spontaneous mutants such as "rump-shaker" model of SPG2 or gene knockout models), typically exhibit much more mild phenotypes than humans with the same or equivalent mutations. Nonetheless, these models have proven valuable in the investigation of pathogenic mechanisms underlying HSP. The occurrence of congenital bovine spinal dysmyelination in American Brown Swiss cattle as a consequence of bovine spastin gene mutation is discussed above.

### 119.8.1 SPG4/Spastin Mutation Mice

*SPG4*/spastin mutations are the single most common cause of autosomal dominant, uncomplicated HSP. Tarade et al. (477) reported studies of *SPG4*/spastin gene mutation mice. The Cre/LoxP gene targeting vector was used to create mice in which *SPG4*/spastin exons 5 through 7 were deleted and replaced by the inserting vector. By crossing mice that were heterozygous for this mutation (*Sp<sup>del/+</sup>*) with either CMV-Cre transgenic mice or with NSE-Cre transgenic animals, mice were created in which the deleted spastin gene was present in all tissues (*Sp<sup>del/+</sup>/CMV-Cre* mice) or only in neurons (*Sp<sup>del/+</sup>/NSE-Cre* mice). In preliminary analysis, some *Sp<sup>del/+</sup>* mice exhibited impaired rotarod performance compared to normal littermates. This phenotype was highly variable, however, indicating the importance of modifying genetic factors.

In our laboratory, we created mice in which the *SPG4*/spastin gene is mutated (J. K. Fink et al. unpublished observations) (476). We observed that mice bearing heterozygous deletion of *SPG4*/spastin mutant exon 8 exhibit age-dependent gait disturbance due to impaired hind limb locomotor ability. These deficits were observed in open field assessment and rotarod performance. *SPG4*

mutant mice older than 1 year tended to walk with hind limbs externally rotated and often demonstrate impaired trunk control, tail dragging, intermittent “scooting” (dragging the hindquarters instead of hind limb stepping), or “hopping” (instead of hind limb stepping).

These observations support the concept that *SPG4*/spastin gene mutations are pathogenic through haploinsufficiency. Although these observations are preliminary, they support “proof of concept” that mice bearing *SPG4*/spastin mutations exhibit a recognizable behavioral phenotype of impaired hind limb motor performance; and the usefulness of these animals to investigate *SPG4* pathogenesis and treatment.

### 119.8.2 *SPG3A*/Atlastin Mutation Mice (478)

Our laboratory also created mice in which the *SPG3A*/atlastin gene is mutated targeted deletion of all of *SPG3A* exon 8 which results in a frameshift and protein truncation after residue 242 (of atlastin’s 559 amino acids). These animals show mild age-dependent hind limb motor impairment, evident in open field evaluation, footprint analysis, and grid-walking and rotating rod assessments. Preliminary neuropathologic studies indicate axonal degeneration involving spinal cord axons, anterior horn cells, and peripheral nerve axons and changes in skeletal muscle consistent with chronic denervation. Lower motor neuron involvement has been reported in *SPG3A* HSP (110).

These preliminary observations support the concept that *SPG3A*/atlastin gene mutations are pathogenic through haploinsufficiency. Observations that mice bearing *SPG3A*/atlastin mutations develop age-dependent gait disturbance and neuropathologic changes similar to humans with *SPG3A*/atlastin mutation indicate that these animals are an important resource in which to explore *SPG3A*/atlastin function, the pathogenesis of *SPG3A*/atlastin mutations, and ultimately, treatments for HSP.

### 119.8.3 *SPG10*/KIF5A Knockout Mice (465)

KIF5A null mice die immediately after birth. Therefore, Xia et al. (465) used a synapsin-promoted Cre-recombinase transgene to create mice in which targeted disruption of the KIF5A gene occurred in neurons postnatally. The majority (75%) of mutant mice developed seizures and died at approximately 3 weeks. Older surviving animals had age-dependent hind limb paralysis, sensory neuron degeneration, accumulation of neurofilament in neuron cell bodies, reduction in axon number, and loss of large caliber axons.

### 119.8.4 *SPG7*/Paraplegin Knockout Mice

Homozygous mutations in *SPG7*/paraplegin cause a rare form of complicated autosomal recessive HSP. *SPG7*

encodes a mitochondrial metalloprotease designated “paraplegin.” Some, but not all, *SPG7* HSP patients have abnormal-appearing mitochondria (“ragged red” fibers and cytochrome C oxidase negative fibers) in biopsies of skeletal muscle.

Ferreirinha et al. (472) reported studies in homozygous *SPG7*/paraplegin knockout mice. These animals displayed impaired performance on rotarod apparatus starting at age 6 months and worsening with age. Spinal cord histology showed axonal swellings (through massive accumulation of organelles and neurofilaments), more prominently in the lateral columns of the lumbar spinal cord. This phenotype was slowly progressive, with signs of axonal degeneration becoming prominent at 12 months of age. Changes in mitochondrial morphology appeared to precede axonal changes in this system, suggesting that degeneration is due to impaired mitochondrial function. This study therefore indicated that *SPG7*/paraplegin gene disruption in mice recapitulates the histologic and, albeit to a lesser extent, the locomotor disturbance of humans with *SPG7* HSP.

### 119.8.5 *SPG39*/NTE Knockout Mice

Akassoglou et al. (479) used Cre-Lox recombination to create mice in which NTE was deleted in neurons. These animals showed prominent neuronal pathology in the hippocampus, thalamus, and cerebellum, disruption of endoplasmic reticulum, vacuolization of nerve cell bodies, and abnormal reticular aggregates.

### 119.8.6 *SPG2*/PLP Mutation Mice (459,460)

PLP is an intrinsic myelin protein. PLP gene mutations cause both PMD, an X-linked leukodystrophy, as well as X-linked HSP (*SPG2*). To some extent, the phenotype depends on the nature of the PLP gene mutation. Although severe disease (PMD leukodystrophy) is usually caused by increased expression of PLP due to gene duplication, a number of PLP point mutations have also been shown to cause PMD. There are naturally occurring mouse models containing PLP mutations (jimmy(jp), jimpy-4J, msd, and rumpshaker); as well as PLP-null mice in which the PLP gene has been disrupted by gene targeting. The phenotype of these animals often depends on the particular mutation and genetic background (480). Depending on the particular mutation, PLP missense mutations and aberrant mRNA splicing mutations result in severe hypomyelination and early death (481–485), or simply tremor and normal life span (486). In contrast, mice in which the PLP gene has been disrupted by gene targeting display length-dependent axonal degeneration that is similar to patients lacking PLP. These studies demonstrate that: (1) genetic background (e.g., the impact of modifying genes) influences the PLP gene mutation phenotype; (2) PLP gene mutations can cause either hypomyelination or primary axonal degeneration; and

(3) axonal degeneration in HSP may arise from a primary glial (oligodendroglia in this case) abnormality.

### 119.8.7 SPG1/L1CAM Knockout Mice

Mutations in L1CAM cause X-linked “CRASH” syndrome, “MASA” syndrome, and X-linked hydrocephalus associated with spastic paraplegia. Depending on the particular mutation introduced, L1CAM knockout mice have shown hind limb motor impairment and reduced size of the corticospinal tracts (456,487); and number of brain defects including reduced size of the corpus callosum and hippocampus, enlarged ventricles, septal abnormalities, and abnormal migration of mesencephalic dopamine neurons (487–489). These results provided evidence that L1CAM plays an important role in brain development, particularly that of corticospinal tracts and the migration of dopamine neuron. Furthermore, studies of L1CAM mutations in humans and mice illustrate that the HSP syndrome may be caused by developmental disturbance of corticospinal tract formation rather than corticospinal tract degeneration.

*Drosophila* models of HSP (SPG4, SPG3A, SPG39): Kammermeier et al. (490) identified the *Drosophila* homolog of spastin (*Dspastin*). Orso et al. (491) created *Drosophila* bearing *Dspastin* insufficiency (via RNA interference [RNAi]) and those overexpressing a neuronally targeted *Dspastin* mutant (*Dspastin* K467R mutant corresponding to pathologic mutation K388R in humans). They observed that loss of *Dspastin* produced adult-onset progressive locomotor impairment, neurodegeneration, and early death; within 15–20 days of age, flies stopped moving and had neurodegeneration in the brain with obvious neuronal apoptosis. Both *Dspastin* deficiency and mutant *Dspastin* expression resulted in excessive stabilization of microtubules in the neuromuscular junction (NMJ) synapse (observations consistent with other evidence of spastin’s microtubule-severing properties discussed above). Moreover, they observed that vinblastine, a microtubule destabilizing drug (but not a functionally related agent nocodazole), significantly attenuated disease-related abnormalities in vivo. At the cellular level, vinblastine treatment was associated with suppression of induced cytoskeletal abnormalities of the neuromuscular synapse. Sherwood et al. (468) generated *Drosophila* bearing *Dspastin* deletions and observed a similar, very severe behavioral phenotype (null mutants were flightless), striking morphological changes in NMJs, reduced synaptic vesicle release, and shorter lift span. Overexpression of *Dspastin* in muscle erased the muscle microtubule network, consistent with other evidence (described above) of spastin’s microtubule severing properties.

The *Drosophila* homolog of NTE is the Swiss Cheese protein (SWS) (492). *Drosophila* *sws* mutants are an important model of NTE mutation-induced neurodegeneration (492). Early death occurs in *sws* flies due to

neuronal vacuolization, apoptosis, and glial hyperwrapping. *sws* is localized to 7D1 on the X chromosome. Therefore, age-dependent neurodegeneration occurs in *hemizygous male and homozygous female sws* flies. *sws* mutations include missense mutations in the esterase/patatin domain and the regulatory domain and a non-sense mutation that yields a truncated protein missing the esterase/patatin domain (6). These are similar to the location of NTE mutations we identified in NTE-MND families. NTE esterase activity measured in the heads of *sws1* mutant flies is decreased as compared to controls (493).

Lee et al. (494) generated atlastin null *Drosophila* and observed age-dependent locomotor impairment (flies were paralyzed by mechanical shock such as being bumped) that was associated with degeneration of dopaminergic neurons. This phenotype could be rescued by targeted expression of wild-type atlastin in dopaminergic neurons or by levodopa administration. On this basis, Albin et al. performed DTBZ-PET scans in humans with SPG3A/atlastin mutation and observed normal nigrostriatal dopaminergic terminal density. This indicates important differences between molecular consequences of atlastin mutation in *Drosophila* and humans.

Subsequently, studies of atlastin null and atlastin-depleted (via RNA interference methods) *Drosophila* provided evidence that atlastin is required for normal growth of muscles and synapses at the NMJ (495), and clearly demonstrated atlastin’s function in endoplasmic membrane fusion (30,496).

## 119.9 CONCLUSIONS

Although the primary symptoms of HSP are insidiously progressive spastic weakness in the legs, it is important to remember that HSP, even when “uncomplicated” or “pure” is not simply a motor neuron disorder affecting corticospinal tracts. Dorsal column fibers are often involved (manifested as mild distal vibratory sense impairment) although typically later and more mildly. The majority of genetic forms of HSP involve peripheral neuropathy or other neurologic abnormalities in at least a subset of patients. The concept that HSP exclusively involves length-dependent distal axonal degeneration involving both motor and sensory fibers is being modified to include neurodegeneration involving shorter axons including those in the cerebellum and those traversing the corpus callosum.

Even in light of the tremendous advances in HSP gene discoveries, for most subjects, HSP is a diagnosis of exclusion. It is imperative that alternative disorders be considered carefully and evaluated by appropriate neurodiagnostic studies.

HSP exhibits extreme genetic heterogeneity. Genetic linkage analyses have identified 51 different HSP loci. Among these, 25 HSP genes have been identified. Discovery of HSP genes has permitted development of

gene-based testing to confirm a clinical diagnosis of HSP (presently available for ~70–80% of dominantly inherited HSP and two forms of X-linked HSP, and for genetic counseling and prenatal testing). Discovery of HSP genes has provided seminal insights into the molecular basis of this large class of motor neuron disorders and permitted development of important animal models. These advances permit direct exploration of HSP's pathophysiology and bring us closer to developing treatments for this group of disorders.

## Autonomic and Sensory Disorders

*Felicia B Axelrod*

NYU Dysautonomia Center, NYU Langone Medical Center, New York, NY, USA

### 120.1 INTRODUCTION

The hereditary sensory and autonomic neuropathies (HSAN) are a group of rare disorders that illustrate the intimate relationship of the development and maintenance of sensory and autonomic neuronal populations. Both neuronal populations derive from the neural crest and develop into unmyelinated neurons by a complicated process of migration and differentiation that can be disrupted by various genetic mutations. Analgesia of varying degree and abnormal autonomic function are common to all the disorders. Because the autonomic nervous system (ANS) is pervasive and integrates multiple functions, symptoms can be widespread and extremely variable (1). Identification and classification of the HSAN disorders are ongoing. In addition to the numerical classification of four distinct forms of hereditary sensory neuropathy that was proposed by Dyck and Ohta (2), additional entities continue to be described (3).

Diagnosis of the various disorders depends primarily on clinical and biochemical evaluations, with pathologic examinations serving to further confirm differences. Some of the disorders have been localized to specific chromosomal regions and specific genetic mutations identified, allowing for definitive diagnoses. With the exception of HSAN type I, which is a dominant disorder presenting in the second decade, that affects serine palmitoyltransferase function and sphingolipid synthesis (4–6), the other HSAN are autosomal recessive disorders whose mutations impede normal neural crest migration and differentiation and result in decreased neuronal populations. Familial dysautonomia (FD) (Riley–Day syndrome or HSAN type III) (3,7,8) and congenital sensory neuropathy (HSAN type IV) (3,9,10) are two such disorders that have been particularly well described and categorized and for which genetic mutations have been identified.

Table 120-1 summarizes some of the other HSAN disorders in which sensory and autonomic functions are

also affected. Table 120-2 lists the specific genetic mutations that have been identified.

### 120.2 FAMILIAL DYSAUTONOMIA

#### 120.2.1 Clinical Features

FD has the most protean nervous system abnormalities of this group of disorders. Pain and temperature sensation are decreased and there is marked autonomic dysfunction (3,7,8). Signs of the disorder are present from birth and neurological function slowly deteriorates with age (3,7,11).

Autonomic dysfunction is pervasive and affects peripheral and central functions. Abnormalities of autonomic function include lack of overflow tears, supersensitivity of the pupil to autonomic drugs, postural hypotension, episodic hypertension, skin blotching, inappropriate hyperhidrosis, and episodic hyperadrenergic vomiting crises.

Earliest signs include feeding difficulties with a poor suck, uncoordinated swallowing, and frequent misdirection of ingested material into the trachea. Recurrent misdirection, especially with liquids, causes aspiration pneumonias and may lead to bronchiectatic disease, atelectasis, and even lung abscesses. Gastroesophageal reflux further increases the risk of aspiration in some patients. Cinesophagrams have demonstrated delay in cricopharyngeal relaxation, abnormal gastrointestinal motility, and reflux.

Vomiting crises associated with irritability, negativistic behavior, hypertension, tachycardia, blotchy erythema, and diaphoresis are observed in 40% of patients. Crises, which may occur as often as once a week, typically last for 1–3 days but can persist for up to 10 days. Dehydration and aspiration of vomitus may be fatal. The crises are associated with elevated circulating serum catecholamines (12).

TABLE 120-1    Affected Neurologic Functions and Genetics of Nine Congenital Sensory Disorders								
Neurologic Function	Congenital Sensory Familial Dysautonomia (HSAN Type III)	Congenital Insensitivity Neuropathy with Anhidrosis (HSAN Type IV)	Congenital to Pain without Anhidrosis (HSAN Type V)	Congenital Autonomic Sensory Neuropathy (HSAN Type II)	Sensory Neuropathy Dysfunction with Universal Pain Loss	Progressive with Skeletal Dysplasia	Hereditary Panneuropathy with Hypotonia	Radiating Neuropathy (HSAN Type I)
<b>Sensory</b>								
Pain	Reduced	Absent	Absent	Absent	Absent	Absent	Reduced	Distal
Temperature	Reduced	Reduced	Normal	Absent	Absent	Absent	Reduced	Distal
Touch	Normal	Reduced	Normal	Absent	Reduced	Reduced	Normal	Reduced
Position sense	Reduced to normal	Normal	Normal	Reduced	?	?	Reduced	Reduced
Visceral pain	Normal	Reduced	?	?	Absent	Reduced	Normal	?
Axon flare	Absent	Absent	Normal	Absent	Absent	Absent	Absent	Local
<b>Reflexes</b>								
Tendon	Hypoactive or absent	Hypoactive or normal	Normal	Hypoactive	Absent	Absent	Absent	Hypoactive or normal
Superficial	Hypoactive or normal	Hypoactive or normal	?	Hypoactive	Absent	Hypoactive	?	Normal
<b>Cranial nerves</b>								
Corneal (V)	Normal, diminished or absent	Absent	Variable	Diminished	Absent	Absent	Diminished	?
Gag (IX, X)	Diminished or normal	Normal	?	Diminished	Diminished	Diminished	Diminished	?
Pain (V)	Reduced	Reduced	?	Absent	Absent	Absent	Reduced	?
Taste (XII)	Reduced	Normal	Normal	Reduced	?	?	Reduced	?
<b>Autonomic</b>								
Sweating	Increased (with stress)	Absent	Normal	Reduced or normal	Increased (with stress)	Reduced	Increased	Reduced
Tear production	Decreased	Normal	Decreased	Normal	Decreased	Normal	Normal, then reduced	Normal
Postural hypotension	Present	May be present	Not present	Not present	Present	?	Present	Normal
G1 motility	Abnormal	Normal	Abnormal	Variably abnormal	Variably abnormal	Abnormal	Abnormal	?
<b>Intelligence</b>	Normal	Decreased	Decreased	Decreased	Decreased	Decreased	Normal	Mild or normal
<b>Genetics</b>	Autosomal recessive	Autosomal recessive	?Autosomal recessive	?Autosomal recessive	?Autosomal recessive	?	Autosomal recessive	Autosomal recessive

**TABLE 120-2 Genetic Mutations Identified for the Hereditary Sensory and Autonomic Neuropathies**

Gene	HSAN	Type	Chromosome
Familial dysautonomia	III9q31	9q31	<i>IKBKAP</i>
Congenital sensory neuropathy with anhidrosis	IV	1q21–22	TrkA/NGF-receptor
Congenital insensitivity to pain without anhidrosis	V	1p11.2–p13.2	NGF-beta chain –
Congenital sensory neuropathy	II	?	?
Congenital autonomic dysfunction with universal pain loss	—	?	?
Congenital sensory neuropathy with skeletal dysplasia	—	?	?
Progressive panneuropathy with hypotonia	—	?	?
Hereditary radicular neuropathy	I	9q22.1–22.3 3q13–22	<i>SPTLC1</i>

Abnormal responses to hypoxic or hypercarbic states compound the problem of aspiration pneumonias and chronic lung disease in FD (13,14). When oxygen tension is lowered (as at high elevations, during air travel or in tunnels) minute ventilation does not increase appropriately. The ensuing hypoxemia may lead to hypotension, bradyarrhythmia, and even syncope. Diving or underwater swimming can be hazardous. Agitated patients are able to hold their breath without discomfort long enough to produce cyanosis, syncope, decerebrate posturing, and seizures. Tachypnea does not accompany respiratory infections.

Consistent lack of overflow emotional tearing is pathognomonic of the disorder. As corneal hypesthesia or anesthesia is a component of the disease, reflex tearing in response to intraconjunctival foreign material is also absent. Although baseline tearing varies among affected individuals, hypesthesia results in a decreased blink frequency and causes rapid evaporation of baseline moisture. The relatively dry eye is then at risk for corneal de-epithelialization, ulceration, and scarring with opacification. The pupil responds appropriately to light and accommodation, suggesting intact parasympathetic pathways, yet is supersensitive to infused methacholine. Abnormal permeability of the damaged cornea might contribute to this sensitivity.

Blotchy erythema occurring during eating or emotional excitement is one indication of abnormal vasomotor control. Supersensitivity to circulating catecholamines, giving rise to hypertension during crises, has already been alluded to. In periods between crises there is supine hypertension, as well as postural hypotension without compensatory tachycardia; heart rate and blood pressure move in parallel, which demonstrates lack of afferent baroreflex feedback (12,15,16). Excitement can cause profuse sweating. The extremities may intermittently become cold, red, and mottled. Inappropriate temperature response to infection or environmental changes can result in either hypothermia or hyperthermia.

Sensory involvement is most prominent in temperature discrimination (11,17). Nevertheless, hypoalgesia is first noted, most often by the blunted response to trauma. Tongue sores on the ventral surface due to repetitive thrusting against newly erupted teeth are

common and there is decreased response to injections, venipuncture and fractures. Although bone and skin pain are poorly perceived, sensitivity to visceral pain is intact. Appropriate responses to pleural effusions, esophageal irritation, and menstrual cramping indicate that there is no central error in the interpretation of pain. These also suggest that not all sensory components of the peripheral nervous system are equally affected. Touch sensation is relatively well preserved and proprioceptive abnormalities appear in older patients (11).

Defective afferent conduction may account for the absence of deep tendon reflexes. Motor neuron involvement may underlie the infantile hypotonia, abnormal gait, and high incidence of juvenile scoliosis in FD. By 10 years of age, 85% of patients have scoliosis. There is a higher incidence of left thoracic curves than in idiopathic scoliosis (18,19).

As a group, patients have average intelligence, with a general tendency for better verbal than motor performance, but developmental milestones are commonly delayed. There is a subgroup of affected individuals with pervasive developmental delay; some of these individuals never develop normal expressive language. Memory is usually excellent but executive planning skills are frequently impaired and there is a tendency to concrete thinking with problems in extrapolation. Seizures with decerebrate posturing can follow breath holding, even in children with normal electroencephalograms (EEGs).

Somatic growth is poor; the average adult height being about 5ft. Growth hormone levels are usually normal but some patients have responded well to growth hormone administration, suggesting decreased responsiveness to physiological levels (20). Puberty is commonly delayed in both sexes. The average age at menarche is 15 years compared with a normal of 12.8 years. Nevertheless, primary and secondary sexual characteristics do eventually develop. Males are capable of erection and ejaculation. Fertility in both males and females has been proved and offspring of affected individuals have been normal.

Progressive diminution of renal function with age is a frequent observation (21,22). Moderate azotemia is an early sign. Creatinine clearance decreases, and many patients have subnormal renin excretion. Progression to

renal failure has led to dialysis for a number of patients as well as renal transplants (23).

### 120.2.2 Genetics

FD is an autosomal recessive disorder that appears to be largely confined to Ashkenazi Jews. In this population, the carrier rate is approximately 1 in 30 with a disease frequency of 1 in 3600 live births. In 1993, the gene for FD was localized to the long arm of chromosome 9 (24). Because one major haplotype was found for over 98% of the FD chromosomes, it was hypothesized that there was one founder mutation for this gene among the Ashkenazim (25).

In 2001, the gene was identified as *IKBKAP* (26,27). FD remains almost exclusive to individuals of Eastern European Jewish extraction. Greater than 99% of individuals with FD are homozygous for a mutation in intron 20: a T to C change located at base pair 6 of intron 20 (IVS20+6T>C) that results in tissue-specific mis-splicing, with variable decrease in expression of the protein product IKAP/ELP1 that is especially profound in neuronal tissue (27). Two other missense mutations have been reported. One mutation, in exon 19, was noted in four unrelated Jewish patients heterozygous for the major splice mutation; the second mutation, in exon 26, was reported in a single patient who was also heterozygous for the major splice mutation but inherited the new mutation from a non-Jewish parent (28).

FD is the only HSAN for which carrier testing of the general population has been recommended.

Now that the gene has been identified, its mode of action must be explored before we can consider that definitive therapies are being explored to either increase general production of IKAP or improve splicing efficiency (29).

### 120.2.3 Diagnosis

Although DNA diagnosis is now available, clinical suspicion is based on the recognition of sensory and autonomic dysfunction that starts at birth. The following criteria are used for clinical confirmation of the disorder. The criteria are listed in order of frequency of observation.

- (1) Signs of sensory dysfunction
  - (a) Absence of fungiform papillae on the tongue and decreased taste
  - (b) Absence of flare after intradermal histamine
  - (c) Decreased or absent deep tendon reflexes
  - (d) Decreased or absent corneal reflexes
  - (e) Decreased response to pain and temperature
- (2) Signs of autonomic dysfunction
  - (a) Absence of overflow tears
  - (b) Miosis following intraocular administration of dilute methacholine 2.5% or pilocarpine 0.0625%
  - (c) Postural hypotension

- (d) Blotching
- (e) Increased sweating
- (f) Episodic hypertension

Further supportive evidence includes feeding difficulties, repeated aspiration, episodes of hypothermia, breath holding spells, hypotonia and delayed motor development, repeated vomiting, abnormal cinesophagram, spinal curvature, poor somatic growth, and Ashkenazi Jewish parentage.

Because individuals affected with the other HSAN disorders will also fail to produce an axon flare after intradermal histamine, careful assessment of the other clinical signs and symptoms is necessary to distinguish between these disorders (3). Because there can be extreme variability in expression, clinical criteria are not always sufficient. In such cases molecular diagnosis is indicated.

### 120.2.4 Pathologic and Biochemical Findings

FD appears to represent a disorder in which there is developmental arrest of the sensory and autonomic systems, with sympathetic development more widely affected than parasympathetic.

Sympathetic ganglia are about one-third the normal size and have only about one-tenth the normal population of neurons (30). The number of neurons tends to be fewer in older patients, but degenerative changes are not prominent. Surviving neurons tend to be slightly larger than normal and to have markedly increased immunoreactive tyrosine hydroxylase (31). Sympathetic terminals are sparse or absent on the vessels of skin, nerves (17,32,33), or kidneys (22). Preganglionic sympathetic neurons in the spinal cord are reduced to about half the normal population (30).

Parasympathetic ganglia are variably affected (34). The ciliary ganglion is normal or marginally depleted of neurons. The sphenopalatine ganglion has less than one-tenth the normal population. Sensory ganglia are also small and have markedly reduced numbers of neurons (35).

Increasing residual nodules and decreasing neurons in older patients indicate a degenerative component. The sensory sural nerve is hypoplastic and contains markedly reduced populations of nonmyelinated and small myelinated fibers and there is lesser depletion of large-myelinated axons (36,37). Lissauer's tract is small in the spinal cord (30). The dorsal columns conducting vibration and proprioceptive and touch information are initially normal but diminish markedly in older patients.

Lingual sensory axons and submucosal neurons are diminished in number (38). Circumvallate papillae are hypoplastic and bear few taste buds. Fungiform papillae are absent and filiform papillae are rudimentary (38,39).

No consistent qualitative central nervous system (CNS) anomalies have been found as yet.

On measurement of urinary catecholamine metabolites, FD patients have been found to have elevated levels of homovanillic acid (HVA) and normal to low levels of vanillylmandelic acid (VMA), resulting in elevated HVA:VMA ratios (40). These findings are consistent with the neuropathological descriptions of a decreased sympathetic neuronal population. Although supine plasma levels of norepinephrine are normal or elevated, FD patients, like most other patients with neurogenic orthostatic hypotension, do not have an appropriate increase in plasma levels of norepinephrine and dopamine  $\beta$ -hydroxylase (D $\beta$ H) with standing (12,16,41). Circulating D $\beta$ H levels have been reported as diminished by Weinshilbaum and Axelrod (42), but this is not apparent when age-matched controls are used (43). In addition, FD patients appear to have a distinctive pattern of plasma levels of catechols (44). Regardless of posture, plasma levels of dopa are disproportionately high and plasma levels of dihydroxyphenylglycol (DHPG) are low, resulting in elevated plasma dopa:DHPG ratios, which are not seen in other disorders associated with neurogenic orthostatic hypotension. During emotional crises, dopamine and norepinephrine are markedly elevated (12).

Patients are also hypersensitive to sympathomimetics and parasympathomimetics. Small doses of methacholine cause profound falls in blood pressure in the absence of compensatory tachycardia. Doses of norepinephrine that would be below threshold in normal subjects cause hypertension; again, there is no cardiac compensation in the form of bradycardia. The pupil is supersensitive to constriction by methacholine but not to dilation by epinephrine.

### 120.2.5 Management

The disease process cannot be arrested. Supportive therapy is directed toward specific problems that vary considerably from patient to patient. Uncoordinated swallowing usually makes breast feeding impossible. A gastrostomy is often required to maintain adequate caloric intake to avoid dehydration and to prevent aspiration (3,7,45).

Pyrexia in response to dehydration, mucous plugs, environmental temperature, or stress is usually brief but associated with muscular spasms and extreme discomfort. Antipyretics may be ineffective and tepid sponging or a cooling mattress may be required. A muscle relaxant such as diazepam is often helpful in reducing spasms and anxiety during pyrexia.

A high index of suspicion for pneumonia should be maintained rather than attributing febrile episodes to the disorder itself. Radiographic examination is often necessary for diagnosis. Pathogens cultured from tracheal aspirations are often uncommon agents requiring use of broad-spectrum antibiotics (46). In individuals with chronic lung disease, postural drainage and inhalation

therapy may have to be used as a daily routine. For those who have sleep-disordered breathing with oxygen desaturations and hypercarbia, noninvasive nocturnal ventilation is suggested.

Breath holding episodes are often interpreted as seizures. They can be frightening but are self-limiting and, in our experience, have never been fatal in normal atmosphere. The cyanosis of breath holding must be differentiated from the cyanosis that can occur with mucous plugs. Either cause of hypoxia can produce seizurelike movements and decerebrate posturing. EEGs are not helpful. The frequency of hypoxic seizures is unaffected by anticonvulsant therapy. Appropriate instructions to parents are indicated regarding underwater swimming, air travel, and visits to high altitudes. Antiepileptic drugs are used in some patients who are thought to have autonomic seizures manifested by daily crises that appear to be provoked by arousal (47).

Corneal complications have been decreasing with regular use of artificial tear solutions containing methylcellulose and maintenance of normal body hydration. Artificial tears are instilled three to six times daily, depending on the child's baseline eye moisture and environmental conditions and on whether the child is febrile or dehydrated. Moisture chamber spectacle attachments help maintain eye moisture and protect the eye from wind and foreign bodies. Tarsorrhaphy of the medial or lateral part of the palpebral fissure has been reserved for unresponsive and chronic situations. Cautery of the tear ducts increases baseline moisture and is beneficial in promoting corneal healing.

Management of a "vomiting crisis" has five goals: (1) adequate hydration, (2) relief of gastric distention to reduce the risk of gastroesophageal reflux and aspiration, (3) suppression of vomiting, (4) relief of hypertension, and (5) induction of sleep (45). The latter seems essential for resolution of a crisis. Dehydration is characteristically isotonic and is best estimated on weight change, as tearing and blood pressure are unreliable indicators. Diazepam is the most effective antiemetic for the dysautonomic vomiting crisis. In addition to its antiemetic effect, diazepam normalizes blood pressure and decreases agitation. Clonidine works in a synergistic manner and aids management of associated diastolic hypertension. H<sub>2</sub> antagonists are useful adjuncts in reducing emesis volume. The crisis usually resolves abruptly and is marked by normalization of personality and return of appetite.

Postural hypotension between crises may respond to increased salt and fluid intake. Caffeinated beverages and waist-high elastic stockings have been helpful. Fludrocortisone and midodrine may be useful in severe cases (48,49).

Decreased response to pain and temperature requires that parents be alert to any unusual swellings or skin discolorations. Smoothing of newly erupted teeth prevents tongue ulcerations in young children. Self-mutilation is rare.

Annual examination of the spine will permit early diagnosis of scoliosis, as well as appropriate institution of brace and exercise therapy. Braces may ulcerate the insensitive skin. The abdominal breathing pattern of these patients may be inhibited and esophageal reflux induced if the brace has a high epigastric projection. Rapid progression and severe curvature at time of presentation are indications for spinal fusion (18,19).

### 120.2.6 Prognosis

With improved supportive measures increasing numbers of patients are reaching adulthood (50). Survival statistics prior to 1960 reveal that 50% of patients died before 5 years of age. Current survival statistics indicate that a newborn with FD has a 50% probability of reaching 40 years of age (50). Many FD adults have been able to achieve independent function. Both men and women with FD have married and reproduced. All offspring have been phenotypically normal despite their obligatory heterozygote state.

Causes of death are less often related to pulmonary complications, indicating that aggressive treatment of aspirations has been beneficial. Of recent concern have been the patients who have succumbed to unexplained deaths, which may have been the result of unopposed vagal stimulation or a sleep abnormality. A few adult patients have died of renal failure.

## 120.3 CONGENITAL SENSORY NEUROPATHY WITH ANHIDROSIS (HSAN TYPE IV)

### 120.3.1 Clinical Features

Congenital sensory neuropathy with anhidrosis (HSAN type IV) is characterized by decreased pain perception, anhidrosis and learning disabilities (9,51,52).

The earliest and most common sign of the disorder is hyperpyrexia. Episodic fevers with extreme hyperpyrexia can be induced by illness and overheating. The fevers can start in infancy and persist throughout the childhood years. Traditionally these febrile episodes have been explained by the inability to sweat. A general defect in thermoregulation, however, actually may be present, as extreme hypothermia has also been observed. With time, the skin may become thick and calloused with lichenification of palms, dystrophic nails, and areas of hypotrichosis on the scalp (3,9,53). As further evidence of autonomic dysfunction, patients exhibit miosis with dilute intraocular methacholine and have mild postural hypotension, but in contrast to patients with FD, there is compensatory tachycardia. Some patients may have a heightened sympathetic response, as erythematous blotching of the skin with excitement has been seen in younger patients. Acrocyanosis is notably lacking.

Other central and peripheral autonomic disturbances are infrequent. On occasion there may be a weak suck, but aspiration is unusual and respiratory problems are not characteristic. Weight gain may be poor. Vomiting is not a feature of the disease. Cyclical crises do not occur and tearing is normal.

Decrease in pain and temperature sensation is extensive and profound, and touch may also be affected (53). Self-inflicted injury is a more prominent feature than in FD (3,9). Biting of lips and fingers and traumatic tongue lesions are common. Injuries to soft tissues, bones, and joints may go unrecognized with subsequent severe secondary changes. Repeated fractures of the lower extremities and poor healing result in aseptic necrosis, Charcot joints, and even frequent osteomyelitis. Visceral sensation is also severely impaired, judged by diminished response to testicular compression and increased intra-esophageal pressure.

Hypotonia is seen in the early years. Although strength and tone normalize as the patient gets older, many patients overstretch their large joints as a means of self-stimulation.

From experience following a number of patients from early childhood to adulthood, it appears that some of the neurological features of the disorder are slowly progressive. Initially, both deep tendon and superficial reflexes are usually preserved. With time, the reflexes may decrease and vibration and joint position sense may become impaired. Cranial nerves are normal, with the exception of pain sensation on the face and corneal reflexes. Spinal curvature has not been described but has been noted in some of our patients. It may be secondary to leg length discrepancies due to repeated fractures of the lower extremities.

Patients tend to be irritable, hyperactive and emotionally labile. Hyperactivity and learning disabilities are prominent. EEGs are normal. Seizure activity and breath holding spells are not characteristic.

### 120.3.2 Genetics

HSAN type IV is caused by mutations of the neurotrophic tyrosine receptor kinase 1 gene (*NTRK1*). The human *NTRK1* gene, located on chromosome 1 (1q21–q22), encodes a receptor tyrosine kinase (RTK) for nerve growth factor (NGF) (9). Binding of NGF to RTK stimulates maturation and functioning of nociceptive sensory and sympathetic neurons. One half of reported cases of this autosomal recessive disorder have occurred in consanguineous marriages. In 1996 it was reported that some HSAN type IV patients from Japan and two brothers from Ecuador had mutations in a gene on chromosome 1 (9,10). Using a candidate gene strategy, the genetic basis for HSAN IV was identified when *NTRK1* loss-of-function mutations were found (10). Since this report numerous mutations have

been identified within the *NTRK1* domain (54). In some cases the mutations seem to correlate with phenotypic expression. For example the mildest patient was the one individual who was compound heterozygous for two different mutations (54).

### 120.3.3 Diagnosis

Consistent features of the disorder include anhidrosis and insensitivity to pain. Some authors believe that severe intellectual disability is also a constant feature, but we have seen a few patients with normal intelligence.

- (1) Signs of sensory dysfunction
  - (a) Absence of flare after intradermal histamine
  - (b) Profoundly decreased response to pain and temperature
  - (c) Decreased visceral sensation
  - (d) Absence of corneal reflexes
- (2) Signs of autonomic dysfunction
  - (a) Hypohidrosis or anhidrosis
  - (b) Episodic fevers
  - (c) Abnormal response to intraocular methacholine 2.5% or pilocarpine 0.0625%
  - (d) Blotching with excitement
  - (e) Mild postural hypotension
  - (f) Absent sympathetic skin response

Supportive evidence includes self-mutilation, hypotrichosis of scalp, and lichenification of skin, history of unrecognized fractures or osteomyelitis, joint injuries, poor somatic growth, hyperactivity, developmental delay, and emotional lability.

### 120.3.4 Pathologic and Biochemical Findings

Virtual absence of unmyelinated fibers has been noted in peripheral nerves and in Lissauer's tract from the spinal cord, and in dorsal root ganglia (55,56). The overall size of the sural nerve is markedly reduced. Skin biopsy morphology of HSAN IV patients reveals deficient C and Ad fibers in the epidermis and absent or hypoplastic dermal sweat glands without innervation (57,58).

Nerve growth factor radioimmunoassay was normal in the serum of four patients but decreased biological activity of fibroblast NGF was observed (59). This is consistent with eventual findings of abnormal receptors for NGF.

Involvement of the sympathetic nervous system terminals is indicated by an increased urinary ratio of homovanillic acid (HVA) to vanillylmandelic acid (VMA) with decreased excretion of VMA, 3-methoxy-4-hydroxyphenylglycol (MHPG), and normetanephrine (NM) (60,61). Intravenous infusion of norepinephrine produces a supersensitive response with hypertension and blotching (61).

Important differentiations from FD are normal tearing, normal deep tendon reflexes, normal taste and presence of fungiform papillae, no swallowing problems, and no vomiting.

### 120.3.5 Management

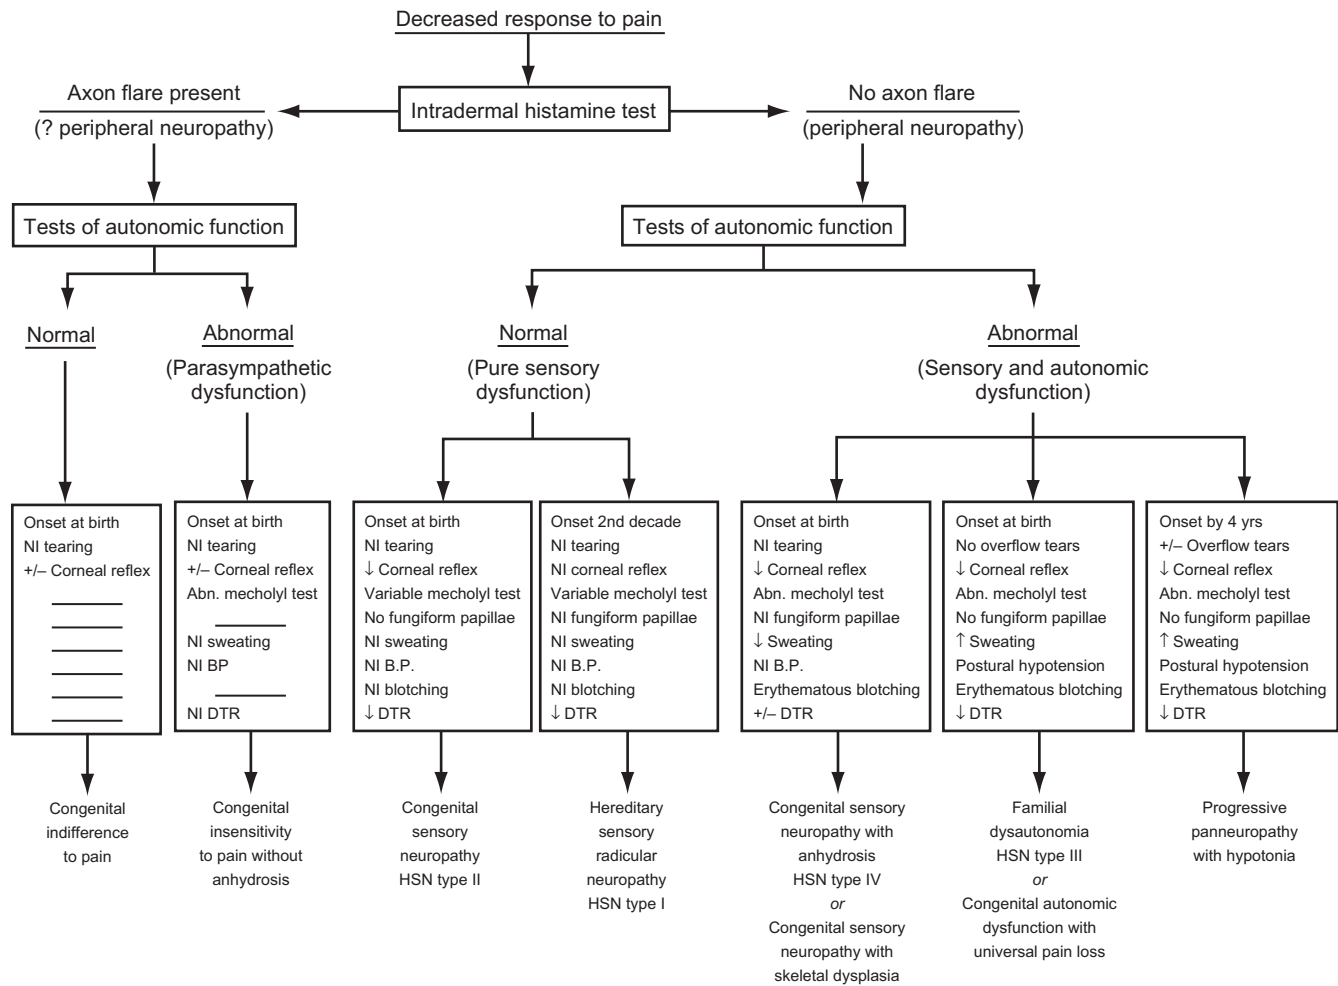

There is no specific treatment for congenital sensory neuropathy with anhidrosis. Extreme care must be taken to guard against inadvertent trauma. The ankles, knees, and fingers are particularly susceptible to injury. Early treatment of traumatic injuries is necessary to prevent secondary degenerative changes. Orthopedic procedures pose major challenges as patients can move within their casts and develop skin breakdown and even osteomyelitis.

Hyperpyrexia can be fatal. Aggressive treatment includes the use of cool baths and sponging and rubbing of the trunk and extremities. Overheating should be avoided and early use of antipyretics is advised. For extreme irritability, chlorpromazine (but not diazepam) has been beneficial. Treatment of the hyperactivity remains difficult, with poor response to stimulants.

### 120.3.6 Differential Diagnosis

Classification of the HSAN remains incomplete and has been complicated by lack of consistency in nomenclature. Each disorder has more than one name and some disorders share the same name. HSAN type II has been used to describe a disorder that is very similar to FD or HSAN type III (3,51) with decreased deep tendon reflexes, absent lingual papillae and decreased response to pain but normal tearing; HSAN type II has been used to describe a disorder characterized by distal neuropathy and trophic ulcers (52). For the former disorder no specific gene has yet been identified but for the latter disorder the causative gene has been reported to be *HSN2* (62), suggesting that term HSAN type II now includes a variety of genotypes.

As illustrated by the two HSAN disorders that are described in detail in this chapter, the HSAN disorders affect both autonomic and sensory function, but there are definite phenotypic differences (Table 120-3). The lack of an axon flare after intradermal histamine is common to all the HSAN disorders, not just FD (3,51,63). By refining clinical studies of the sensory and autonomic function, and with further information regarding neuropathology, distinctions between the other HSAN disorders should become clearer and permit accurate classification. Although the schematic outline in Figure 120-1 provides a helpful preliminary approach to differential diagnosis, it is anticipated that this will be modified as new entities are described. As more of the genetic mutations are identified, diagnosis can be more exact and facilitate genetic counseling.

**FIGURE 120-1** Evaluation of the patient with decreased response to pain. NI, normal; BP, blood pressure; DTR, deep tendon reflex.

Several conditions should be considered in the differential diagnosis of the HSANs. When sensory dysfunction is suspected, because of a history of self-mutilation or decreased responsiveness to pain, great care should be taken to document that there is sensory dysfunction rather than a behavioral or metabolic abnormality, as might occur with either cognitive impairment or Lesch–Nyhan syndrome. If sensory dysfunction is then confirmed, it should be determined which sensations are abnormal, the degree of the abnormality, and the somatic distribution. Loss of touch, pressure, vibration, and joint position senses occur in the autosomal recessive disorder Friedreich ataxia. Vibration and position sense in deep tissues are lost in Refsum disease,

but cutaneous sensation tends to remain intact. In dysraphia and syringomyelia pain pathways may be interrupted at a secondary neuronal level in the spinal cord.

When both autonomic and sensory functions are impaired, one must determine which sympathetic, parasympathetic, and enteric dysfunctions are present. Variable combinations of autonomic and sensory dysfunction may be observed in children with mitochondrial myopathies (64). Perturbations in autonomic and sensory function due to diabetes mellitus, Fabry disease, and amyloidosis is present in the adult years. Isolated autonomic dysfunction associated with developmental anomalies of neurons occur in hypertrophic pyloric stenosis and Hirschsprung disease.

**TABLE 120-3 The Eight Sensory Disorders with Peripheral Neuropathy and Their Pathologic Findings**

	<b>Familial Dysautonomia (HSAN Type III)</b>	<b>Congenital Sensory Neuropathy with Anhidrosis (HSAN Type IV)</b>	<b>Congenital Insensitivity to Pain without Anhidrosis (HSAN Type V)</b>	<b>Congenital Sensory Neuropathy (HSAN Type II)</b>	<b>Congenital Autonomic Dysfunction with Universal Pain Loss</b>	<b>Congenital Sensory Neuropathy with Skeletal Dysplasia</b>	<b>Progressive Panneuropathy with Hypo-</b>
Sural nerve	Decreased total size	Marked reduction in total size			Marked reduction in total size	Normal overall nerve size; faint myelin stain; ballooning of inner laminae	?
	Small myelinated fibers slightly decreased	Normal myelinated population	Large myelinated fibers are reduced	Severe depletion of myelinated axons	Marked decrease in myelinated fibers	Marked decrease in myelinated fibers	?
	Unmyelinated fibers markedly decreased (about 25% of normal)	Severe reduction in unmyelinated fibers (about 5–10% of normal)	Unmyelinated fibers normal	Moderate decrease in unmyelinated fibers	Only slight decrease in unmyelinated fibers	Unmyelinated fibers normal	?
Sensory ganglia	Decreased total size, decreased neuronal count, residual nodules; increase in number with age	Absence of thin myelinated fibers; absence of small neurons	?	?	?	?	Extremely small; only residual nodules remaining in ganglion
Sympathetic ganglia	1/3 of normal size 1/10 number of neurons; increased proportion of tyrosine hydroxylase	Normal	?	?	?	?	?

### Biography

**Dr Felicia B Axelrod** is Professor of Pediatrics and Neurology at the NYU School of Medicine. Her career has focused on understanding and treating rare hereditary sensory and autonomic disorders (HSAN). Her initial body of work dealt with familial dysautonomia (FD) but then she expanded her interest to other disorders affecting development of the autonomic and sensory nervous systems. With the support of the Dysautonomia Foundation and NYU Medical Center she founded the Dysautonomia Treatment and Evaluation Center in 1970. Dr Axelrod has centralized the care of patients with FD resulting in new treatments and dramatically lengthening of life expectancy. In collaboration with Harvard University, Dr Axelrod identified the responsible genetic mutation for FD. This has lead to prenatal testing and global population screening, which has successfully reduced the number of new cases to less than 5 per year worldwide.

Dr Axelrod was awarded the Carl Seaman Family Professor Chair for Dysautonomia Treatment and Research in 1992. NYU School of Medicine awarded her the Soloman A Berson Medical Alumni Achievement Award in Health Science in 1998 and the Samuel Leidesdorf Alumni Award in 2003. She was a past President of the American Autonomic Society and the David H Streeten Lecturer.

### 121.1 INTRODUCTION

The term phakomatosis derives from phakos, the Greek word for birthmark. It was originally used by van der Hoeve in 1923 (1) to describe neurofibromatosis and tuberous sclerosis. von Hippel–Lindau (VHL) disease was added in 1932 (2) and Sturge–Weber syndrome (SWS) in 1936 (3). As other neurocutaneous diseases of a spotty or patchy nature have been recognized, they have been incorporated into the spectrum of the phakomatoses. A list of disorders that have been classified with the phakomatoses is presented in Table 121-1. In this chapter, we consider the original conditions included by van der Hoeve, as well as some of the more common ones listed in the table.

### 121.2 THE NEUROFIBROMATOSES

Until the late 1970s, many publications did not distinguish between the different forms of neurofibromatosis and used von Recklinghausen disease or multiple neurofibromatosis as all-encompassing terms. We now recognize three distinct forms of neurofibromatosis: neurofibromatosis type 1 (NF1), neurofibromatosis type 2 (NF2), and schwannomatosis (Table 121-1). Although each disorder is characterized by multiple nerve sheath tumors, the natural history for each disorder is different and each is due to mutations in a distinct gene.

#### 121.2.1 Neurofibromatosis Type 1 (NF1)

NF1 is the form of neurofibromatosis described by von Recklinghausen and was formerly referred to as von Recklinghausen disease or peripheral neurofibromatosis. It is the most common form of the disease and one of the most common single gene disorders. Most studies have found a disease prevalence of around 1 in 3000 (4,5). Evans et al. (6) estimated the disease prevalence of NF1 at 1 in 4560 and birth incidence at 1 in 2699.

**121.2.1.1 Clinical Features.** The clinical features of NF1 and the age of presentation are summarized in Table 121-2. The phenotype tends to evolve with age and is highly variable, both within and between families.

**121.2.1.1.1 Café-au-Lait Spots and Freckling.** Café-au-lait spots (Figure 121-1) are usually the first feature to appear; some may be present at birth, and they continue to develop and increase in size until puberty. In the diagnostic criteria, six or more café-au-lait spots are required because one to three spots are a relatively frequent finding in approximately 10–15% of the general population (7). The number of café-au-lait spots decreases with time, as they fade and disappear in adulthood (8). There is no correlation of the location of café-au-lait spots of average diameter less than 10 cm with the location of other NF1-associated lesions, such as neurofibromas, and there is no correlation of the overall number of café-au-lait spots with the severity of the disorder. Some plexiform neurofibromas have café-au-lait pigmentation overlying them, and this can be the first obvious change in early childhood (9). Therefore, particularly large areas of pigmentation need to be monitored for plexiform change. Such areas often have irregular edges. Café au lait spots vary in diameter, but are mainly less than 10 cm. They usually have smooth contours, but some, particularly the larger ones, have irregular outlines. Their color intensity varies with background skin pigmentation (10). Occasionally, in children with very pale complexions, café-au-lait spots may be difficult to see with the naked eye and are best assessed with a Wood's lamp.

The other characteristic pigmentation, which appears to be unique to NF1, is freckling in specific body areas not related to sun exposure (11). The classical area for freckling is the axilla, but it is also seen around the base of the neck, the groin, and the submammary region in women. These resemble café-au-lait spots (1–3 mm in

TABLE 121-1 The Phakomatoses

Disorder	Frequency	Gene	Major Features
NF1	1:3000	<i>NF1</i> ; GAP protein	Café-au-lait macules, neurofibromas, optic gliomas, malignant peripheral nerve sheath tumors, learning disabilities, skeletal dysplasias
NF2	1:33,000	<i>NF2</i> ; cytoskeletal protein	Vestibular schwannomas, meningiomas, ependymomas, cataracts
Schwannomatosis	Unknown	<i>SMARCB1</i> ; chromatin remodeling protein	Schwannomas of peripheral nerves, pain
Tuberous sclerosis complex	1:6000	<i>TSC1/TSC2</i> ; mTOR regulator	Hypomelanotic macules; angiofibroma; cortical tubers; seizures; intellectual disability; renal angiomyolipomas; cardiac rhabdomyomas
von Hippel–Lindau syndrome	1:40,000	<i>VHL</i> ; angiogenesis regulator	Hemangioblastomas of cerebellum, brainstem, spinal cord, retina; renal cell carcinoma; pheochromocytoma
PTEN hamartoma syndrome	Rare	<i>PTEN</i> ; cell signaling protein	
Proteus syndrome	Rare	<i>AKT1</i> ; cell signaling protein	Bony and cutaneous overgrowth; disfigurement

diameter) and develop after the café-au-lait spots appear, usually between 3 and 5 years of age (12). Some patients have small freckles all over the trunk.

**121.2.1.1.2 Peripheral Neurofibromas.** Nearly all adult patients with NF1 have neurofibromas (see Figure 121-1). Those within the epidermis are soft on palpation and may become papillomatous. Neurofibromas located deeper within the dermis often have an overlying violaceous color. Neurofibromas under the surface of the skin or deeper in the body have a nodular configuration and are firm in texture. The number of neurofibromas is only roughly proportional to age; severely and mildly affected cases can be seen in all age groups beginning in the teens (8,13). At present there is no means of predicting the number of neurofibromas someone will develop, with the exception that individuals with deletions of the entire *NF1* gene tend to develop large numbers of neurofibromas (14). Neurofibromas most commonly appear at times of hormonal change, including puberty and pregnancy (15). One study did not reveal an increase in the rate of growth of neurofibromas in women using oral contraceptives, except in two women receiving a high-dose depot form of progesterone (16).

Dermal lesions are rarely painful, although some patients complain of pruritis (9). Numerous lesions present a significant cosmetic burden (17). Dermal neurofibromas rarely, if ever, undergo sarcomatous change. Deeper nodular neurofibromas may give rise to neurologic symptoms due to nerve compression and are painful, particularly to pressure.

In addition to neurofibromas, glomus tumors have been identified in some individuals with NF1. These occur at the tips of the digits and present with pain that can be relieved with tumor resection (18).

**121.2.1.1.3 Plexiform Neurofibromas.** Plexiform neurofibromas involve multiple fascicles of a nerve, extending along the length of the nerve and involving multiple branches (19). In the Welsh study, 26.7% of patients had plexiform neurofibromas (13); 1.2% had

large facial plexiform neurofibromas of the head and neck (associated with major cosmetic problems) and 5.8% had large lesions of the trunk or limbs associated with significant skin hypertrophy or overgrowth of the underlying bone (Figure 121-2). Imaging studies reveal a higher frequency of plexiform neurofibromas than may be apparent clinically, with whole body magnetic resonance imaging (MRI) studies showing 50–100% of patients having plexiform tumors (20–22). Plexiform neurofibromas, particularly those with extensive internal involvement, may undergo malignant change.

Plexiform neurofibromas are clinically and pathologically distinct from dermal neurofibromas. There are two types of plexiform neurofibromas. The most common present as large subcutaneous swellings with ill-defined margins and vary from a few centimeters in diameter to those involving a whole area of the body. Their consistency is usually soft, although sometimes hypertrophic nerve trunks can be palpated within the mass. The skin overlying the lesion is often abnormal because of a combination of hypertrophy, hyperpigmentation, and hypertrichosis. Unless it is very obvious that the lesion is limited to the skin, an MRI scan should be considered to delineate the extent of internal involvement. Tumors that invade skin may have a diffuse appearance by MRI (23). Patterns of growth differ depending on whether the tumors are superficial or invasive (24), and lesions often undergo rapid growth in the early years of life, after which they remain relatively quiescent, growing only in proportion to body growth (25). Aside from disfigurement, some may impinge on critical structures such as the airway or urinary tract and thereby cause significant morbidity (26,27). Surgery is difficult because of the diffuse nature of the lesions and because they may be very vascular (28); recurrence after surgery is related to the degree of resection (29).

The other form of plexiform neurofibroma is the nodular variant. In these lesions, the nerve trunks develop multiple nodular neurofibromas that merge into one

**TABLE 121-2 NF1 Clinical Features and Age of Onset**

Disease Feature	Frequency (%) <sup>a</sup>	Age at Presentation
Café-au-lait spots	>99	0–2 y
Skinfold freckling	67	3–5 y
Peripheral neurofibromas	>99	≥7 y
Plexiform neurofibromas		
All lesions	30	0–18 y

Glomus tumors of nailbeds	<1	Adulthood

<sup>a</sup>Data from Huson and colleagues (13).<sup>b</sup>Data from Mautner and colleagues (524).<sup>c</sup>Optic glioma is seen in 15% of children if imaging study is done (56).<sup>d</sup>Lifetime risk may be 5–10% (98).<sup>e</sup>Data from Riccardi and Eichner (525).<sup>f</sup>See Takazawa and colleagues (101).**FIGURE 121-1** The major defining features of NF1. Café-au-lait spots and cutaneous neurofibromas in an adult with NF1. (From Huson S. M. *Neurofibromatosis 1: A Clinical and Genetic Overview*. In Huson S. M.; Hughes R. A. C.; Eds.; *The Neurofibromatoses: A Pathogenetic and Clinical Overview*. Chapman and Hall, London, 1994, pp 176. Reproduced with permission of Edward Arnold.)

another. They may involve one nerve or a whole plexus of nerves. The patient usually presents because of pain related to the lesions. If they involve a relatively superficial nerve trunk, they present as smooth subcutaneous masses, which are often painful on palpation. When deeper nerve trunks are involved, the lesions are only detectable on imaging (30,31).

**121.2.1.1.4 Lisch Nodules.** Lisch nodules are asymptomatic iris hamartomas. They can occasionally be seen with the naked eye, but slit-lamp examination is preferable to distinguish them from common iris nevi (Figure 121-3). On slit-lamp examination, they have a smooth, dome-shaped appearance and are usually light brown, although some can be very pale (32). They develop during childhood, after the appearance of café-au-lait spots but before peripheral neurofibromas and so may be useful in confirming the diagnosis of NF1 in children with no family history and only multiple café-au-lait spots (12). They are highly specific for NF1 and are present in over 90% of affected adults (33,34).

**FIGURE 121-2** Plexiform neurofibromas. (A) Facial plexiform neurofibroma in a 2-month-old girl. (B) Plexiform neurofibroma of left leg, associated with limb overgrowth, in a 38-year-old man. He had required epiphyseal plating of the tibia to prevent further overgrowth as a teenager. (From Huson S. M. *Neurofibromatosis 1: A Clinical and Genetic Overview*. In Huson S.M.; Hughes R. A. C.; Eds.; *The Neurofibromatoses: A Pathogenetic and Clinical Overview*. Chapman and Hall, London, 1994, pp 177. Reproduced with permission of Edward Arnold.)

**FIGURE 121-3** Lisch nodules.

#### 121.2.1.1.5 Macrocephaly and Short Stature.

Macrocephaly and short stature are common in NF1 but are not specific to the condition and therefore cannot be used as diagnostic criteria. Macrocephaly was found in 45% of the Welsh population (13), and 31.5% of individuals were at or below the third centile for height. Growth curves have been produced for use in individuals affected with NF1 (35).

**121.2.1.1.6 Learning Difficulties.** All the population-based studies of NF1 have shown that at least 25–30% of patients require educational assistance because of learning difficulties (36). Hyman et al. (37) found academic difficulties in 52% of children with NF1, of which one-third had lowered IQ. Specific learning disabilities in those with normal IQ included problems with attention, planning, visuospatial skills, and language. Those without learning difficulties did have minor problems with sustained attention, planning, and visuospatial skills. Comorbid attention deficit disorder with hyperactivity was found in 38% of children. The situation is further compounded by coordination problems in NF1-affected children (38–41). Behavior problems and sleep disturbance also occur with increased frequency (42,43). Cognitive problems appear to begin early in life (44) and do not improve with age (45).

The pathogenesis of learning difficulties in NF1 patients is undetermined. Some authors have found a correlation between the number of enhanced T2-weighted signal abnormalities seen in NF1 on MRI (46,47) or their location in the thalamus (Moore 1996) but others have not found this correlation (48,49). Evidence for frontal cortical dysfunction has been obtained from functional MRI studies (50), and MRI morphometric studies have shown gyral anomalies (51) or increased size of the

corpus callosum (52,53) that may contribute to learning problems. Studies in a mouse model suggest that dysfunction of the Ras signaling pathway due to NF1 haploinsufficiency may be responsible for learning problems (54).

It is important to be vigilant for learning problems and neuropsychological assessment should be provided for those in whom learning problems are suspected. If children are found to have very severe learning problems or moderate to severe intellectual disability, then it is important to ensure that the child does not have a complication of NF1 such as hydrocephalus secondary to aqueduct stenosis. Children with deletions of the entire *NF1* gene also may display severe cognitive impairment (55). If these NF1-related causes of severe learning impairment are excluded, then other causes should be considered, such as fragile X syndrome.

**121.2.1.1.7 Optic Glioma.** Approximately 15% of children with NF1 display thickening of the optic nerve visualized by computed tomography (CT) or MRI (56–58). Although biopsy is rarely done, this is attributed to optic glioma; in cases in which biopsy has been done, the pathology is typically pilocytic astrocytoma. Optic glioma may involve the orbital portion of the optic nerves, the retro-orbital portion, the chiasm, or any combination of these components. Orbital optic glioma can produce proptosis, interference with extraocular movements, and loss of visual acuity or visual fields. Visual loss can also occur from retro-orbital or chiasmatic tumors, and the latter can involve the hypothalamus, usually presenting as precocious puberty (59,60), which may be accompanied by growth hormone excess (61).

Asymptomatic children in whom optic gliomas are diagnosed incidentally by MRI should be followed up clinically with repeated ophthalmologic assessment and MRI but is not treated unless visual impairment (loss of visual acuity or fields or proptosis) occurs (56). Spontaneous plateau of tumor growth is common, and regression has been seen even in untreated patients (62–64). In the past, symptomatic optic gliomas were treated with radiation, but cranial radiation in young children results in a high frequency of cognitive, endocrine, and vascular complications (65). Chemotherapy is more commonly used now, particularly vincristine and carboplatin (66–68), although many affected children continue to lose vision following treatment (69,70). Surgery is rarely indicated, since the diagnosis does not require biopsy and there is a high likelihood of visual impairment after surgery. Surgical treatment is reserved for orbital tumors that are causing pain or proptosis.

**121.2.1.1.8 Skeletal Dysplasia.** Long bone dysplasia, most commonly involving the tibia and sometimes also the fibula (71), occurs in approximately 3% of individuals with NF1 (72). Other long bones can be involved more rarely. Dysplastic bone includes cortical thickening (73) and medullary canal narrowing, and there may

be cystic changes (74,75). Usually there is no associated neurofibroma in the region. Long bone dysplasia occurs congenitally and usually is clinically evident during the first year of life as anterolateral bowing. Dysplasia of the greater wing of the sphenoid may occur, usually in association with orbital plexiform neurofibroma (76). This can lead to enophthalmos, or, if there is orbital tumor, exophthalmos. Dysplastic vertebrae may occur, causing a dystrophic scoliosis, most commonly involving the thoracic spine. Nondystrophic scoliosis also occurs at an increased frequency (77). There can also be bone cysts that can result in fracture, although most are asymptomatic. Individuals with NF1 have been reported to have decreased bone mineral density, reduced vitamin D levels, and increased risk of fracture (78–84). Osetoclast activity has also been reported to be higher in NF1-affected individuals (85) and osteoblast function is reduced (86).

**121.2.1.1.9 Cardiovascular Complications.** Cardiovascular complications are an important source of morbidity and even mortality. Arterial occlusions may occur due to nodular proliferation of spindle-shaped cells in the arterial wall and can cause renovascular hypertension (87–89), aneurysm, arterial dissection, and cerebrovascular occlusion and moyamoya disease (90,91). Congenital heart defects, particularly pulmonic stenosis, are also seen with increased frequency (92,93). NF1 patients with hypertension should also be evaluated for pheochromocytoma (94). Instances of pulmonary hypertension in adults with NF1 have also been reported (95–97).

**121.2.1.1.10 Malignant Tumors.** The lifetime risk of malignancy (excluding optic glioma) in NF1 has been estimated at approximately 8–13% (98); Walker et al. (99) estimated a risk of 20% by 50 years of age. Major tumor types include gliomas, malignant peripheral nerve sheath tumors (MPNST), leukemia, rhabdomyosarcoma, pheochromocytoma, and gastrointestinal stromal cell tumors (100,101). One study indicates a moderately increased risk of breast cancer in women with NF1 (102). Gliomas may occur anywhere in the central nervous system (CNS) and are seen in both adults and children. Most are low-grade pilocytic astrocytomas, but more aggressive tumors can occur (103–106). Care must be taken in distinguishing gliomas from benign foci of enhanced T2 signal intensity. MPNST are highly aggressive sarcomas that usually arise from preexisting plexiform neurofibromas or nodular neurofibromas. Although they are most common in young adults, children can be affected (107). Sudden growth or unexplained pain is a sign of malignancy, but diagnosis can be difficult since the malignant tumor often lies adjacent to a preexisting benign neurofibroma. MRI findings may be helpful in distinguishing benign from malignant tumors, with signs such as peripheral enhancement or edema and cystic appearance suggestive of malignant change (108). Positron emission tomography with [18F]-deoxyglucose may be useful,

revealing enhanced uptake in MPNST (109–114). Some MPNST have features of rhabdomyosarcoma. The relative risk of leukemia is increased in NF1, particularly nonlymphocytic leukemia (115). Some children with NF1 develop juvenile xanthogranuloma (JXG) (small yellowish nodules on the skin, seen especially near the hairline, in early childhood) (116,117). JXG can also be seen in individuals with myeloid leukemia, but it is not established that JXG in children with NF1 is predictive of leukemia.

**121.2.1.2 Diagnostic Criteria.** NF1 is diagnosed using clinical criteria set forth by the National Institutes of Health (NIH) Consensus Development Conference (118,119). An individual who fulfills two or more criteria can be diagnosed as having NF1. Many of the features are age dependent, however, so children who have a single feature, such as multiple café-au-lait macules, often must be followed for several years before a second feature is seen (120). The use of MRI to detect foci of enhanced T2 signal has been proposed as a diagnostic criterion, but the specificity of this finding is unclear (121). Genetic testing is now available to help resolve uncertain diagnoses (see below). The NIH Consensus Development Conference Statement diagnostic criteria for NF1 are met in an individual who has two or more of the following:

- (1) Six or more café-au-lait macules of over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
- (2) Two or more neurofibromas of any type or one plexiform neurofibroma
- (3) Freckling in the axillary or inguinal regions
- (4) Optic glioma
- (5) Two or more Lisch nodules (iris hamartomas)
- (6) A distinctive osseous lesion such as sphenoid dysplasia or long bone dysplasia
- (7) A first-degree relative (parent, sibling, or offspring) with NF1 by the above criteria

These criteria have stood the test of time well. Individuals with Legius syndrome or homozygous mutation of mismatch repair genes may also fulfill NF1 diagnostic criteria. These entities are discussed in detail below.

**121.2.1.2.1 Segmental or Localized NF1.** The term segmental or localized NF1 is used to describe the patients with disease features limited to one or more body segment. Ruggieri and Huson (122) have reported their series of 124 patients with segmental NF1. They estimated a prevalence between 1 in 36,000 and 1 in 40,000 individuals in the general population. Most patients were asymptomatic and sought medical opinion because of the unusual appearance of the skin. In the majority, the area involved was unilateral and varied in size from a narrow strip to one quadrant and occasionally one half of the body. Some patients had more than one segment involved on both sides of the midline, either in a symmetrical or

an asymmetrical arrangement. Within the affected area, the patients either had NF1-related pigmentary changes, neurofibromas alone, or both. Eight of the 124 patients had a solitary plexiform neurofibroma as their only manifestation. Seven of the remaining 116 patients (6.9%) had specific NF1 complications, including learning difficulties, plexiform neurofibromas, optic pathway gliomas, and pseudarthrosis. Other NF1 complications were only identified in patients with segmental pigmentary changes. Mosaicism for NF1 mutation can be demonstrated in most cases, sometimes in blood but otherwise in Schwann cells from neurofibromas or melanocytes from café-au-lait macules (123). The importance of recognizing this group is for their different natural history and because they have much lower recurrence risks in offspring. There are, however, well-recorded examples of parents with segmental NF1 having children with full-blown NF1 (124).

**121.2.1.3 Differential Diagnosis.** NF2 should be considered in assessing children or teenagers with a few café-au-lait spots (usually six or less) in association with any other NF2 features. One should be particularly cautious in children with multiple nodular peripheral nerve lesions—the clinical appearance of peripheral schwannomas in NF2 is similar to that of peripheral nodular neurofibromas in NF1. A useful distinguishing feature of NF2 is the cutaneous NF2 plaque. Young children who have six or more café-au-lait spots and no family history should be followed up. They usually have NF1, and other disease features gradually appear (12). Café-au-lait spots can be seen in association with other syndromes, such as tuberous sclerosis complex (TSC), ataxia telangiectasia, and Noonan syndrome, although other features of these conditions should establish the correct diagnosis. Rare individuals with homozygous mutation of mismatch repair genes have presented with multiple café-au-lait spots and skin fold freckling, thereby fulfilling diagnostic criteria for NF1. Most of these individuals die at a young age of malignancies (125–133).

Brems et al. (134) reported five families with autosomal dominant transmission of multiple café-au-lait spots, with or without skin fold freckling, macrocephaly, and learning disabilities associated with mutation in the *SPRED1* gene. *SPRED1* is a negative regulator of Ras, which is the target of the product of the *NF1* gene. This condition has come to be known as “Legius syndrome.” Subsequent analysis has indicated that affected individuals do not appear to be at risk for tumors associated with NF1, such as neurofibromas, optic gliomas, or malignancies (135). Cognitive impairment is also not as significant as for patients with NF1 (136). Implications for genetic testing will be discussed below.

**121.2.1.4 Natural History.** NF1 is characterized by a wide range of phenotypic variability, both between and within families. The major morbidity and mortality in NF1 is caused by the occurrence of disease complications, many of which present in childhood or not at all (see Table 121-3). Individuals with NF1 face a decreased

**TABLE 121-3 NF2 Clinical Features**

Feature	Frequency (%)

Data from Evans et al. (205) and Asthagiri et al. (526).

overall life expectancy (137–140). Major causes of death related to NF1 are malignancy and vascular complications such as hypertension and hemorrhage.

**121.2.1.5 Genetics.** NF1 is an autosomal dominant condition with variable expression but virtually 100% penetrance by the age of 5 years (5,13). Approximately 50% of cases represent new mutations, and the mutation rate is one of the highest recorded in humans. Crowe and colleagues (4) estimated a mutation rate on the order of  $1.4\text{--}2.6 \times 10^{-4}$ , although subsequent studies have shown a lower rate,  $3\text{--}6.6 \times 10^{-5}$  (5,141). The reasons for the extreme variability in NF1 are unknown. Studies of concordance in twin pairs (142,143) indicate that some features, such as number of café-au-lait spots and average number of tumors, are concordant, whereas others, such as presence of plexiform neurofibromas, are not concordant. This suggests that both genetic factors, including the *NF1* mutation and other modifying loci, as well as nongenetic or stochastic factors are involved in determining the specific NF1 phenotype.

**121.2.1.5.1 Genetic Testing.** Genetic testing is available for NF1 and can be used to assist in diagnosis of affected individuals and for prenatal testing. Given the large size of the gene (>350kb) and the large diversity of mutations, multiple approaches need to be used to achieve nearly complete ascertainment of mutations

(144). Most mutations lead to loss of function of the gene product, either due to deletion of the gene or due to premature termination of translation due to stop mutation, frameshift, or abnormal splicing. Only a few genotype–phenotype correlations have been reported. These include a severe phenotype (large tumor burden, developmental impairment, and dysmorphic features) in those with large deletions that encompass the entire *NF1* gene and several nearby genes (14,145), absence of neurofibromas in those with a specific three-base deletion in exon 17 (146), and presence of nodular, spinal, and extensive plexiform neurofibromas with minimal dermal involvement with missense or splicing mutations (147,148).

Given the relative paucity of genotype–phenotype correlations, *NF1* genetic testing is not useful in those where a definitive clinical diagnosis has been established, unless prenatal diagnosis is desired. It can be useful establishing an NF1 diagnosis in a young child who presents with a single NF1 feature, such as multiple café-au-lait spots. It may take several years before a child will develop additional signs of NF1. Although clinical management is currently limited to surveillance, establishing a definite diagnosis can be reassuring to some parents. Genetic testing can also distinguish between Legius syndrome and NF1, which can be important given the more benign course of Legius syndrome. Legius syndrome is much less common than NF1, so genetic testing for *NF1* mutation is likely to be more productive than *SPRED1* (135). The highest proportions of *SPRED1*-positive patients are postpubertal individuals with multiple café-au-lait spots, no NF1-related tumors, and a family history of similar manifestations.

**121.2.1.5.2 Genetic Counseling.** The 50% risk to offspring of an affected individual is straightforward; more difficult to share with families is the varied and unpredictable nature of the disease. If children at risk of NF1 have not developed multiple café-au-lait spots by the end of their second year of life, then it is very likely that they have not inherited the *NF1* gene. In the 50% of cases with no family history, recurrence risk for the parents is minimal. Examination of the skin and eyes of the parents is important, as children with NF1 have been born to parents with segmental neurofibromatosis (124) or Lisch nodules only. These parents represent gonosomal mosaics. Pure gonadal mosaicism is a rare event in NF1 (149).

**121.2.1.6 Pathogenesis.** *NF1* was identified in 1990 (150–153). The gene spans over 350kb of genomic DNA, consists of 60 exons, and encodes a 2818-amino-acid protein referred to as neurofibromin (154,155). There are three additional genes (*EV12A*, *EV12B*, and the oligodendrocyte myelin glycoprotein gene [*OMGP*]) located within intron 27B of *NF1*. The transcriptional orientation of the three intronic genes is reversed compared to that of *NF1*.

Neurofibromin has a domain homologous to the GTPase-activating protein (GAP) family (152,156,157).

This region is known as the GAP-related domain (NF1-GRD) and accounts for about 13% of the gene sequence. Neurofibromin is involved in the regulation of the signal transduction molecule Ras, stimulating conversion of Ras-GTP to Ras-GDP. The mechanism whereby increased Ras-GTP leads to neurofibroma formation remains unclear. Studies have shown hyperactivity of the mammalian target of rapamycin (mTOR) pathway in neurofibromin-deficient astrocytes, suggesting another potential target for development of therapeutics for NF1 (158–160).

Dominant inheritance of NF1 coupled with the occurrence of multiple tumors at multiple sites throughout life have suggested the possibility that NF1 might function as a tumor suppressor, analogous to hereditary retinoblastoma. This predicts that both copies of *NF1* would be mutated in a tumor such as a neurofibroma, with one mutation representing the inherited change and the other being acquired somatically. Loss of heterozygosity for NF1 or biallelic mutation has been demonstrated in MPNST (161), leukemias (162), bone dysplasias (163), melanocytes in café-au-lait macules (123), and Schwann cells in neurofibromas in NF1 patients (164–169). MPNST tend to accumulate additional genetic changes besides biallelic *NF1* mutation (170), as is common in malignant tumors.

The tumor suppressor hypothesis is also supported by animal models. Mice with an *Nf1* knockout mutation do not develop neurofibromas or other classical signs of NF1, but do get sarcomas and leukemias (171,172). Homozygous animals die in early development due to cardiovascular anomalies (173), but mice that are rendered chimeric for *Nf1*<sup>-/-</sup> cells on a wild-type background develop plexiform neurofibromas (171). Conditional knockout strategies have been used to generate models that develop plexiform neurofibromas (174), optic gliomas (175), dermal neurofibromas (176), vascular dysplasia (177), and skeletal dysplasia (178,179).

Although the tumor suppressor mechanism in Schwann cells appears to be the primary cellular event in neurofibroma formation, there is evidence for a role of haploinsufficiency of NF1 expression in other cells, particularly mast cells (180,181), being necessary for tumor formation (174). Studies of mast cells from *Nf1* mice (182–185) have revealed abnormal proliferation of these cells and hypersensitivity to growth factors. Furthermore, in animal studies, loss of NF1 function in Schwann cells does not result in neurofibroma formation if the gene is normal in all other cell types. Tumor formation only occurs with nullizygous Schwann cells on a heterozygous background. The origin of *-/-* cells in neurofibromas is also a matter of investigation. Dermal neurofibromas appear to arise from Schwann cell precursor cells in the skin (176,186); plexiform neurofibromas most likely arise from embryonic Schwann cells (187), which explains their typical congenital appearance.

**121.2.1.7 Management.** It is recommended that individuals with NF1 have an annual clinical review (119). Since the purpose of the clinical assessment is to detect complications, the age of presentation of the various complications (see Table 121-3) must be appreciated so that an appropriate assessment can be offered to patients of different ages. In the first 2 years of life, one is particularly monitoring for plexiform neurofibromas, sphenoid wing dysplasia, and tibial dysplasia. Neuropsychological assessments become important in preschool children. Children should have annual ophthalmological evaluations to screen for visual dysfunction; tests of visual fields may be difficult, but visual acuity should be possible to assess (188). Apart from learning difficulties and plexiform neurofibromas, most complications of NF1 present with symptoms. The exception to this is hypertension due to renal artery stenosis or pheochromocytoma, so the annual review for all ages must include measurement of blood pressure. There are no specific treatments for any of the disease features. Patients with cosmetic problems need the support of a plastic surgeon.

In our opinion, none of the complications warrants screening investigations, although this is a matter of debate, particularly with regard to the role of routine cranial MRI scans. Cranial MRI scans in children with NF1 will detect optic gliomas in 15%, the majority of which will remain asymptomatic, and in 60% enhanced signal intensity will be found on T2-weighted or fluid-attenuated inversion recovery (FLAIR) images (189). Occasionally, other asymptomatic lesions with mass effect are also observed, particularly in the brainstem; if an asymptomatic lesion or an optic glioma is detected, follow-up scans and clinical assessments are needed. In our opinion, the detection of these asymptomatic lesions does not alter clinical management, as they are treated only if symptomatic and their detection often only serves to increase parental anxiety, but other authors have advocated MRI screening for the early detection of optic glioma (190).

We advocate the value of the specialist neurofibromatosis clinic. In this setting, patients are offered coordinated care and follow-up by a group of health professionals, including a pediatrician, ophthalmologist, dermatologist, neurologist, neurosurgeon, orthopedic surgeon, otolaryngologist, plastic surgeon, geneticist, specialist genetic nurse/genetic counselor, social worker, and psychologist. Usually one of the group acts as the overall coordinator of patient care and involves the others at certain times in the patient's life or because of specific symptoms. The clinic is used for family support when NF1 is newly diagnosed, for specialist genetic counseling, and for assessment of unusual symptoms or complications.

Insights into pathogenesis and the availability of mouse models are providing an opportunity to perform drug screening. Previous trials of ketotifen (a mast cell stabilizer) (191), interferon alpha-2a, cis-retinoic acid,

thalidomide (192), pirfenidone (193), and tipifarnib (194) have not revealed definitive evidence of effectiveness. One case has been reported indicating shrinkage of a plexiform neurofibroma treated with imatinib (184); this finding is being followed up in a phase II clinical trial. Neurocognitive improvement has been noted in *Nf1*<sup>+/-</sup> mice treated with lovastatin. One trial in humans with simvastatin did not show definitive improvement (195), but additional studies with statins administered to children with documented neurocognitive impairment are underway (196).

## 121.2.2 Neurofibromatosis Type 2

Writing in the twenty-first century with easy availability of MRI scans and molecular genetic knowledge, it is hard to see how the different forms of neurofibromatosis were ever considered to be one disease (197–199). The overlap with NF1 occurs because some cases of NF2, particularly the severe form that presents in childhood, may initially present with cutaneous features that overlap with NF1. NF2 was not established as a distinct entity until 1970 (200). The other factor that caused confusion was the pathological nomenclature for different nerve tumors. The main lesions in NF2 are on the vestibular branch of the eighth nerve and are schwannomas, yet formerly they were always referred to as acoustic neuromas. Hence NF2 was formerly referred to as bilateral acoustic or central neurofibromatosis. The 1991 NIH Consensus Development Conference Statement on Acoustic Neuroma (201) recommended replacing the term acoustic neuroma with vestibular schwannoma.

NF2 is much less common than NF1, with a prevalence of around 1 in 60,000 and an estimated birth incidence of 1 in 33,000 (202).

**121.2.2.1 Clinical Features.** NF2 causes significantly more morbidity and mortality than other forms of neurofibromatosis largely due to vestibular schwannomas and other cranial or spinal tumors (197,202–204). The frequency of the different clinical features is shown in Table 121-3. MRI scans often show NF2 patients to have multiple lesions, a significant proportion of which will never need treatment (202–204).

**121.2.2.1.1 Vestibular Schwannomas.** Vestibular schwannomas are the most consistent disease feature and were present bilaterally (and symptomatic) in 85% and 92.1% of cases in two large series (203,205). A further 6% of cases in both studies had unilateral vestibular schwannomas. The presenting symptoms of NF2 are related to vestibular schwannomas in the majority of affected individuals (202–204). Early symptoms include hearing loss with tinnitus or vertigo related to pressure on the cochlear nerve. Vestibular schwannomas are usually diagnosed synchronously, but there may be a time interval in their development; in 10 of 58 cases with vestibular schwannomas, Parry and associates (203) report a mean interval of 7.5 years (range,

0.5–20 years) between diagnosis of the first and second tumor.

**121.2.2.1.2 Other Cranial Tumors.** Schwannomas can develop on other cranial nerves and were found on cranial MRI in 51% of 83 cases in one study (206). They can develop on any nerve except one and two, which are CNS derived. They are most frequent on the third, fifth and seventh cranial nerves. Seventh nerve tumors are often only identified at surgery for a vestibular schwannoma (197,206). Many of these never cause major problems and, if so, do not require treatment. Lesions of the lower cranial nerves can cause significant morbidity if symptomatic because of swallowing problems. Cranial meningiomas are found in approximately 50% of patients in cross-sectional studies (207), although some will never cause problems. Optic nerve meningiomas are seen in NF2 much more frequently than in the general population and are a particular problem as curative surgery is difficult (198,207).

**121.2.2.1.3 Spinal Tumors.** The most frequent spinal tumors in NF2 are dorsal root schwannomas. They usually originate within the vertebral canal and extend both within and out of the canal giving rise to a “dumbbell” appearance on scan. Spinal meningiomas are less common but do occur. NF2-related intramedullary tumors are usually ependymomas histologically, although both astrocytomas and intramedullary schwannomas also occur (197,208–211). Many spinal tumors seen on scan will never cause significant problems; for example, two series documented an overall frequency of spinal tumors of 75% and 89% of patients, but only 26% of these were symptomatic (203,204).

In assessing potential cases of NF2 one must be aware of frequent nosologic confusion between schwannomas and neurofibromas. Spinal schwannomas can appear identical with the spinal neurofibromas seen in NF1, both radiologically and at surgery. Although schwannomas and neurofibromas have distinctive histologic appearances, we have seen a significant number of NF2 patients in whom spinal and peripheral lesions were initially reported as neurofibromas, which were actually schwannomas.

**121.2.2.1.4 Other CNS Manifestations.** Imaging and postmortem studies have shown a number of other abnormalities that are usually not associated with symptoms. Benign intracranial calcifications on CT scans, similar to those seen in tuberous sclerosis, do occur (212). When present they are seen in the choroid plexus, cerebellum, and cerebral parenchyma.

Meningioangiomas is often only diagnosed on postmortem. It is a multifocal cortical plaque-like proliferation (213). Histologically there is a meningotheial and vascular component. The other lesion seen in postmortem studies is glial microhamatoma in the cortex and basal ganglia (214).

**121.2.2.1.5 Peripheral Nerve Tumors.** There are three main types of peripheral nerve tumor in NF2. These have different clinical features, but on histologic

examination are usually schwannomas. Rarely, histology will show mixed appearance of both schwannoma and neurofibroma or even just neurofibroma. The most common peripheral tumors, occurring in 48% of patients in the Evans et al. study (205), are referred to as NF2 plaques and have a distinctive appearance (Figure 121-4). They are discrete, well-circumscribed, slightly raised, cutaneous lesions, usually less than 2 cm in diameter. Their surface is roughened, they may be slightly pigmented, and the overlying skin is often hairy. The second type of peripheral nerve tumors are nodular, subcutaneous lesions on peripheral nerve and were present in 43% of patients in the Evans et al. study. These tumors are clinically indistinguishable from their NF1 counterpart, as are the least common type of peripheral tumors, which appear similar to the dermal lesions of NF1. These were found in 7% of patients in the Evans et al. study, but were fewer in number than would normally be seen in an adult with NF1. Rare patients, usually with severe NF2, have lesions that are clinically similar to diffuse plexiform neurofibromas. Again, on histology these usually have the features of plexiform schwannomas.

**121.2.2.1.6 Café-au-Lait Spots.** As can be seen in Table 121-4, more cases of NF2 than expected have a few café-au-lait spots, but only the occasional patient has six or more (205). The café-au-lait spots are not associated with other NF1 pigmentary abnormalities such as axillary freckling.

**121.2.2.1.7 Ophthalmologic Features.** Eye problems in NF2 fall in to two categories: (1) Primary NF2-related eye lesions such as cataracts and congenital retinal/disk problems, which usually present in childhood

and (2) problems occurring secondary to cranial nerve palsies caused either from an NF2-related tumor or operative nerve damage. In a condition where the patient will almost certainly lose all/some hearing, loss of vision can be a major issue.

The commonest eye findings are cataracts, which were present in 81% of patients in the series reported by Parry et al. (203); 72.4% had posterior capsular cataracts, 41.4% had cortical cataracts, and 32.8% had both types. Fortunately they only cause significant visual disturbance in a minority of cases (two of 47 individuals in the Parry et al. series). Other ocular features in NF2 are much less frequent (215–220) and include retinal hamartomas (either combined pigment epithelium and retinal hamartomas or astrocytic hamartomas) and epiretinal membranes. Whether these cause symptoms depends on position. Even in the absence of a causative lesion, more than the expected number of NF2 patients have no useful vision in one eye—34% (24/73) patients had only unocular vision in one series (220); there was also a high frequency of strabismus.

Secondary eye problems often relate to facial or trigeminal nerve damage at the time of vestibular schwannoma treatment (ptosis, nystagmus, reduced tear production, corneal insensitivity). Schwannomas on the relevant nerves can affect eye movement. Optic nerve meningiomas usually result in visual loss.

**121.2.2.1.8 Peripheral Neuropathies.** In addition to loss of nerve function related to tumors, NF2 patients are also at risk of two forms of peripheral neuropathy: an axonal neuropathy (221,222) and focal amyotrophy (223). The latter presents as a relatively sudden onset of

**FIGURE 121-4** NF2. (A) Cutaneous NF2 plaque. (B) Coronal T1-weighted gadolinium-enhanced MRI demonstrating severe NF2 in an 18-year-old. There are bilateral vestibular schwannomas, an intrinsic brainstem lesion, and a left convexity meningioma. (From Short P. M.; Martuza R. L.; Huson S. See text for sources of data.

weakness and wasting of specific muscle groups causing, for example, facial weakness or foot drop. These neuropathies are thought to result from compression effects of multiple tumorlets, by local influences of the endoneurial pathological cells and/or the inability of these cells to properly adhere to the axon (221). In the clinical study of Evans et al. (205) 6% had a clinical peripheral neuropathy and 4% evidence of focal amyotrophy. When patients have detailed neurological and neurophysiological studies, two-thirds show electrophysiological evidence of peripheral neuropathy, the majority of who are asymptomatic (221).

**121.2.2.1.9 Other Manifestations.** The possibility of NF2 vascular involvement has been raised by cases reports of renal artery stenosis and cerebrovascular problems (224). Although mesothelioma occurs at an increased frequency in *Nf2* +/- mouse models, there have only been occasional reports in NF2 patients exposed to asbestos may have an increased risk of mesothelioma (225).

**121.2.2.2 Diagnostic Criteria.** The original NIH neurologic criteria (118) were too narrow for routine clinical use (205). The Manchester diagnostic criteria are now most widely used and have been found to improve sensitivity without affecting specificity (225). Using these criteria, NF2 is diagnosed in any individual with one of the following criteria:

Bilateral vestibular schwannomas

First-degree relative with NF2 and

–Unilateral vestibular schwannoma *or*

–Any two of meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities

Unilateral vestibular schwannoma *and* any two of meningioma schwannoma, glioma, neurofibroma, and posterior subcapsular lenticular opacities

Multiple meningioma (two or more) *plus* unilateral VS *or* any two of glioma, schwannoma, neurofibroma, and posterior subcapsular lenticular opacities

**121.2.2.3 Differential Diagnosis.** With improvements in neuroimaging, the diagnosis of NF2 is now usually straightforward on clinical grounds. The main time the diagnosis is missed is in children, with no family history, who present with marked cutaneous features and a diagnosis of NF1 is considered. The most helpful features to distinguish the two conditions are the much lower number of café-au-lait spots and the absence of axillary freckling in NF2 and the finding of NF2 plaques. Another problem is that NF2 is not considered in young people presenting with single vestibular or spinal schwannomas and meningiomas. After treatment, they are not followed up and re-present when other tumors become symptomatic. Diagnosing sporadic pediatric cases early is important, as they go on to develop severe NF2 with multiple neuraxis lesions (227,228). The vestibular lesions in such cases can reach a considerable size before causing

symptoms; detection at an earlier stage offers the chance of much improved treatment outcomes.

Multiple meningiomas not associated with other tumors is a recognized, although extremely rare, autosomal dominant trait (229,230). In one family in which meningiomas and ependymomas were segregating as dominant, Pulst et al. (231) excluded linkage to markers that flanked the NF2 locus. The underlying genetic mechanism has not yet been elucidated (232). The diagnosis of familial non-NF2 meningiomas can only be made with a clear family history. In sporadic cases, the causes include NF2 mosaicism, noncontiguous spread of a single sporadic tumor, or new mutation in the as yet unidentified gene(s) responsible for non-NF2 familial meningiomas.

Autosomal dominant inheritance of spinal and peripheral schwannomas without vestibular nerve lesions is seen in schwannomatosis, which is discussed later. From a practical viewpoint, isolated cases of multiple meningiomas or schwannomas should be assessed as if they have NF2, as it is probable they have mosaic NF2. Finally in sporadic cases with no peripheral manifestations, there have been reports of other causes of cerebellopontine angle lesions being initially diagnosed as bilateral vestibular schwannoma (233).

**121.2.2.4 Natural History.** First symptoms usually develop around the age of 20 years on average, but with a range varying from infancy to the sixth decade (203,205,234). These studies showed an average delay of 7 years to diagnosis; again with a considerable range—from 5 to 66 years in the Evans study (205). Fortunately, with increased awareness and routine use of cranial MRI in investigating hearing loss, such long delays are now rare in clinical practice. Our recent clinical experience suggests the cases sometimes still missed at an early stage are children with no family history who present with NF2-related eye or skin problems or an isolated schwannoma or meningiomas.

Nearly all patients eventually develop symptoms related to the vestibular schwannomas and typically progress to bilateral deafness, although this can take many years in mild cases (235). Large vestibular schwannomas may not cause hearing loss and the patient then presents with symptoms related to brain stem compression. The larger the tumor at the time of surgery, the higher the frequency of complications such as facial nerve palsy and bulbar problems.

The number of other neuraxis tumors makes a significant contribution to disease-related morbidity and mortality. Two studies have shown that the age of death is inversely proportional to the age of diagnosis (234,236). Children presenting with symptomatic NF2 have the worst prognosis, as they have multiple neuraxis tumors in addition to bilateral vestibular schwannomas. At the other end of the spectrum are adults with just bilateral vestibular schwannomas presenting in middle age.

In the large UK study reported in 1992 (205) the mean actuarial survival was 62 years, although over

40% would be expected to have died by 50 years. In a Japanese study of 74 cases (234), the overall 5-, 10- and 20-year survival rates were 80, 60 and 28% respectively. Analysis of patients presenting after 25 years gave survival rates of 100, 87 and 62%. It is likely that future studies will show significant improvement relating to modern imaging techniques, developments in microsurgical technique and increasing recognition of the need for treatment in a specialist center.

In the most severe cases, there are so many tumors and other disease-related morbidities, such as loss of vision and neuropathies, that, despite surgery, the patient has significant neurological disability in early adulthood. For these patients, the development of possible systemic treatments discussed below will be of major benefit.

The final factor affecting mortality is treatment center. Baser et al. (236) showed that the relative risk of mortality in patients treated in one of three UK specialist centers was 0.34 compared with those treated in nonspecialist centers.

#### 121.2.2.5 Genetics.

**121.2.2.5.1 Inheritance and Mutation Rate.** NF2 is inherited as an autosomal dominant condition with almost complete penetrance by the age of 60 years (237). Approximately half the cases are sporadic, and approximately one-third of this group is somatic mosaics (238,239). Depending on the timing of the somatic mutation, mosaic NF2 patients present with either mild, generalized or more localized disease, for example, a unilateral vestibular schwannoma with one or more ipsilateral NF2-related tumors. In contrast to NF1, all studies of the clinical course of the disease in NF2 have shown strong intrafamilial correlation but marked interfamilial variation. The exception to this is affected children of a mosaic parent. Earlier studies suggesting a maternal effect on disease severity have not been confirmed (203).

**121.2.2.5.2 The NF2 Gene.** Cytogenetic studies of meningiomas showing frequent loss of chromosome 22 provided the clue to the chromosomal localization of NF2. Seizinger et al. (240) studied loss of heterozygosity of DNA for chromosome 22 markers in vestibular schwannomas from both isolated and NF2 cases. Their positive findings gave strong circumstantial evidence to the location of NF2, which was subsequently confirmed by linkage studies (241). Further studies identified flanking markers and showed no suggestion of locus heterogeneity (242,243).

The identification of a number of germline deletions in NF2 patients in this area facilitated the cloning of the disease gene by two groups (244,245). The gene spans 110kb and has 16 constitutive exons and one alternatively spliced exon. The gene encodes for a 69kDa protein called merlin or Schwannomin (commonly known as merlin).

**121.2.2.5.3 Genotype–Phenotype Correlation.** Clinical studies prior to the molecular era, led to the suggestion

of at least two types of NF2 (203). They suggested there were mild families, which they named Gardner after the first author of the paper of an illustrative family, where the main problems related to the bilateral vestibular schwannomas with few other tumors, relatively late presentation and slow progression. At the other extreme were severe cases, named Wishart, with multiple neuraxis and peripheral NF2 tumors, with a young age of presentation often from other tumors than the vestibular schwannomas. In these cases disease course was rapid with severe disability or death at a young age. There were, however, some families that overlapped the two extremes. The clinical subtypes are now rarely referred to, as clinically useful genotype–phenotype correlation has emerged.

Genotype–phenotype correlation studies have provided a molecular explanation for the interfamilial heterogeneity:

Constitutional nonsense or frameshift mutations are associated with severe disease regardless of their position in the gene (246,247). In studies of spinal involvement, truncating mutations correlate with an increased number of spinal tumors (208,209).

Missense and in-frame or large deletions are associated with mild disease (246,248). Missense mutations are associated with the mildest disease, with a lower risk of mortality (236).

Splicing mutations have been associated with various levels of severity, although disease may be milder if in the 3' end of the gene (249,250).

Mutations in the 3' half of the gene, especially exons 14–16 are associated with a lower risk of meningioma (251).

**121.2.2.5.4 Ring Chromosome 22 and Other NF2-Associated Chromosome Abnormalities.** In a small proportion of cases, NF2 develops because of a constitutional chromosome abnormality (252). These include balanced reciprocal translocations with breakpoints through or near to the NF2 gene (252,253); therefore if no mutation is found on molecular analysis, cytogenetic studies should be done. Patients with ring chromosome 22 are at risk of developing NF2 (252,254). These patients usually present in early childhood with moderate–severe developmental delay, absent expressive speech, and variable facial dysmorphism. As the ring chromosome is prone to loss during mitotic cell division, carriers of the ring may become monosomic for chromosome 22 and lose one NF2 allele, thus they are effectively NF2 mosaics and a mutation in the second allele will give rise to an NF2-related tumor. Zirn et al. (254) review the clinical picture in 10 cases, and this ranges from full blown NF2 to just multiple meningiomas. The age of symptomatic tumor diagnosis ranged from puberty to 52 years. It is therefore important that regular assessments for NF2-related problems is undertaken and continued into adulthood.

**121.2.2.6 Pathogenesis.** The NF2 gene acts as a tumor suppressor in the pathogenesis of schwannomas and other NF2-associated tumors. Somatic inactivation of both alleles also happens in sporadic schwannomas (>90%), meningiomas (50%), and ependymomas (5%) (197,255). NF2 mutations are also seen frequently in sporadic mesotheliomas and less commonly in thyroid cancer and melanoma. Animal models have also demonstrated the tumor suppressor function (256–258). NF2<sup>−/−</sup> genotypes are embryonic lethal in both mice and *Drosophila*, suggesting a vital role in embryogenesis. NF2<sup>+/−</sup> mice develop metastatic osteosarcomas, fibrosarcomas, and hepatocellular carcinomas, but not NF2-related tumors. The best NF2 models result from selective inactivation of NF2 in Schwann cells or leptomeningeal cells, which produces schwannomas and meningiomas, respectively (259). Two major isoforms of merlin exist (1 and 11); only isoform 1 is able to undergo the protein folding that enables the tumor suppressor activity (260–262).

**121.2.2.7 NF2 Protein (Merlin).** The NF2 gene sequence shows strong homology to the highly conserved protein 4.1 family. The NF2-encoded protein is most similar to moezin, ezrin, and radixin and it was named merlin for moezin–ezrin–radixin-like protein (245). The primary role of the protein 4.1 family appears to be in mediating communication between the extracellular milieu and cytoskeleton (263–265). In normal cells, merlin is expressed diffusely across several cell types including Schwann, meningeal, mesothelial, and lens cells.

Merlin is a multifunctional protein involved in integrating and regulating the extracellular cues and intracellular signaling pathways that control cell fate, shape, proliferation, survival and motility (reviewed in (266–268)). The main merlin functions identified to date involve:

Regulating cell–cell and cell–matrix adhesions and functions of the cell surface and extracellular matrix receptors such as CD44.

Stabilizing the contact inhibition of proliferation and regulating activities of several receptor tyrosine kinases including the ErbB family, platelet-derived growth factor receptor  $\beta$ , insulin-like growth factor 1 receptor, and vascular endothelial growth factor (VEGF).

Through these different roles merlin affects downstream signaling of several signaling pathways that are critical for cell growth, protein translation and cellular proliferation including the phosphoinositide-3 (PI3K) pathway, the mitogen-activated protein kinase pathway (MAPK) and mTOR complex 1 (mTORC1) pathway.

**121.2.2.8 Candidate Drugs.** The identification of the signaling pathways affected by merlin dysregulation is now translating in to preclinical and clinical trials (269). Drugs targeting the key pathways such as lapatinib (ErbB1/2 inhibitor) and Platelet Derived Growth Factor

Receptor (PDGFR) inhibitors (nilotinib, sorafenib) are in early-phase human trials. The first drug that has been shown to be effective in growth control of NF2-related vestibular schwannomas is bevacizumab (270,271). Bevacizumab is a monoclonal antibody that binds all biologically active forms of human VEGF, and VEGFs are widely expressed in vestibular schwannoma (270). In a series of 10 NF2 patients at risk of complete hearing loss, Plotkin et al. (270) reported reduction in tumor volume  $\geq 20\%$  in six of 10 patients. In four of seven evaluable patients there was significantly improved hearing. Mautner et al. (271) reported similar response in two patients. Further trials are ongoing and confirming these response rates. Recent case reports suggest that when the drug is stopped the radiographic and clinical benefit is reversed (272). Bevacizumab has had little effect on meningiomas in these cases, and as it affects wound healing, surgery can only be scheduled after the drug has cleared the system (269).

**121.2.2.9 Management.** The successful management of NF2 patients involves coordination between several different specialties, principally neurosurgeons, otolaryngologists, neurologists, ophthalmologists, geneticists and increasingly neurooncologists. Ideally patients are seen in a multidisciplinary clinic (273). Patients also need ongoing support from other health professionals, such as teachers of communication to the deaf and social workers. Treatment in a specialist center has been shown to be associated with a decrease in disease-related mortality (225). This is probably related to two aspects of care: the improved outcome of vestibular schwannoma surgery in specialized centers (269,274,275) and the expert knowledge of disease natural history, recognizing that many tumors seen on scan in NF2 will never need treatment. It is therefore important that patients are referred to such centers as soon as the diagnosis has been made.

The overall aim of NF2 care is to maintain function whenever possible. Improved microsurgical techniques and the development of cochlear/auditory brainstem implants has made this increasingly possible (269,273). The mainstay of management is at least annual clinical, audiological and radiological monitoring of tumors. The only tumors that may be treated before causing symptoms are the vestibular schwannomas, as early surgery on small tumors provides the opportunity for hearing preservation surgery or at least cochlear nerve preservation. The latter allows the opportunity for a cochlear nerve implant, which provides more useful hearing than the auditory brain stem implant. To avoid the complications of surgery, stereotactic radiation therapy can be used for the treatment of vestibular schwannomas less than 3 cm in diameter; although as for surgical outcomes, the results of treatment in NF2 are not as good as for sporadic vestibular schwannomas (276,277). There are now reports of malignant change following radiation therapy, bringing its use into question, at least for younger patients (278).

**121.2.2.10 Genetic Counseling.** Although inheritance is autosomal dominant, genetic counseling is more complicated than usual because of the high frequency of mosaicism in sporadic cases (238,239). The risks given and tissues submitted for mutation analysis will vary according to whether the consultand is the first case in the family or not (279). Evans et al. (279) provide a guideline for genetic counseling and management of at-risk individuals in NF2. In established families the risk to children is 50% and there is relatively strong intrafamilial correlation of disease severity. Molecular analysis is now able to assist the counseling process in the majority of families, providing the options of preimplantation, and prenatal and presymptomatic diagnoses.

**121.2.2.10.1 Mutation Testing.** Using sequence analysis and multiplex ligation-dependent probe amplification (MLPA) the disease causing mutation is identified in around 93% of individuals in the second or subsequent generations of NF2 families (279). As a result of mosaicism, this falls to around 60% in sporadic patients with typical NF2 (Evans 2007) and is very low in patients with an atypical presentation that suggests mosaicism (e.g. a unilateral vestibular schwannoma and ipsilateral schwannomas/meningiomas). The detection rate is also age dependent in people presenting with bilateral vestibular schwannomas; it is 86% in sporadic cases presenting under 20 years of age but this falls to 39% in those presenting with bilateral vestibular schwannomas after 40 years (279). In rare families with no mutation, DNA marker studies can be used.

In sporadic patients with no mutation found in lymphocyte DNA, mutation analysis in two or more tumors usually identifies the causative mutation. If only one tumor is available but both mutations are found, then at-risk children can be tested for both. If only loss of heterozygosity is shown, then this is still useful for counseling at-risk children. If they inherit the allele lost in the tumor they are at very low risk, because this allele is unlikely to have a disease-causing mutation (239). Tumor analysis can either be on tumor tissue taken at the time of neurosurgery or on peripheral tumors specifically removed for genetic analysis.

**121.2.2.11 Genetic Risks for First-Degree Relatives of Nonmosaic Sporadic Cases.** Parents and siblings: If the relatives do not have any symptoms it is unlikely they are affected, but mutation testing can be offered for reassurance. There has been a single case of germline mosaicism reported (203).

Children: The children will have a 50% risk.

**121.2.2.12 Risks for First-Degree Relatives of Mosaic Sporadic Cases.** Parents and siblings: Can be completely reassured, as by implication the proband has had a somatic mutation.

Children: The risk is lower than 50% and is affected by several factors; the risk is increased if the mutation is present in detectable levels in lymphocyte DNA, the parent had a young age of onset and with bilateral rather than a unilateral vestibular schwannoma, or other

combination of NF2 features (239,279). Although the risk is lower, if the child does inherit the mutation the disease is likely to be more severe. The recent UK guideline (279) provides risk levels and management plans for various mosaic presentations at different ages.

**121.2.2.13 Counseling Individuals with Possible NF2.** With increasing awareness of NF2 presentations in childhood (228,280), families may be referred for genetic counseling when their child has presented with, for example, an isolated vestibular schwannoma or meningioma or a typical NF2 retinal hamartoma. These patients should have a full clinical NF2 evaluation and mutation testing. If the results are normal then there is still a risk of a missed mutation or mosaicism; Evans et al. (281) provide follow-up guidelines depending on the clinical scenario.

**121.2.2.14 Management of At-Risk Children.** As the disease can be symptomatic in early childhood and screening is recommended, parents should know that genetic testing is available from early childhood. In our experience, many families defer the genetic testing until around the age of 10, when the at-risk individual can take part in the counseling process. The timing of genetic testing in children is an individual choice for families.

For a child at risk, the first screening test is in infancy when an ophthalmic check is recommended to exclude NF2-related problems that will affect vision. After this, unless the family has particularly severe disease, there is no need for regular review or scans, unless the child develops symptoms or the parent has concerns, until the age of 10. Some families prefer annual review with audiology from infancy. Scans are indicated before the age of 10 only if there are clinical concerns. From the age of 10, annual review with audiological assessment and a cranial MRI is recommended. There should also be a baseline spinal MRI but this only needs repetition every 3 years or if new symptoms develop (199).

In rare families where no genetic testing is available, cranial and spinal MRI at age 10 years is recommended if no tumor is identified. Evans et al. (199) recommend semiannual cranial scans in the teens, reducing to every 3 years from 20–35 years. If the patient wants to be ultra-cautious then annual audiology should be carried out between scans. The spinal scans are repeated every 5–10 years. If no tumor is found by the age of 35 years then the patient can be reassured.

Once an asymptomatic gene carrier has been identified or NF2 is diagnosed in a child with no family history, it is recommended that he or she be cared for by a specialist NF2 clinic so the chances of hearing preservation can be optimized, either through surgery on small tumors or through optimal use of brain stem/cochlear implants.

### 121.2.3 Schwannomatosis

Although not recognized as a form of neurofibromatosis by the NIH Consensus Development Conference (118),

an entity referred to as schwannomatosis is now recognized as a distinct form of neurofibromatosis (282–284). The frequency of schwannomatosis is not known, but it is less common than NF2. A proportion of cases have been shown to have germline mutations in the *SMARCB1* gene (also known as *INI1*, *SNF5* and *BAF47*), which lies proximal to NF2 on chromosome 22 (285). Mutations in the same gene are also associated with malignant rhabdoid tumors (MRTs) (286,287); although MRTs were not originally recorded in schwannomatosis, since the finding of the shared pathogenesis, several families with both MRTs and schwannomas have been reported (286–289).

**121.2.3.1 Clinical Features.** Patients with schwannomatosis develop peripheral nerve and spinal root schwannomas almost exclusively, but with no dermal tumors. These tumors often cause persistent problems with pain. Meningiomas occur rarely. There is no eye involvement and ependymomas have not been seen (282–284,290,291). Cranial nerve involvement is less common than in NF2 and nearly always involves nerves other than the vestibular nerve (292). Malignant transformation of schwannomas in schwannomatosis has been reported, although it seems to be a very rare occurrence (289,293). It is therefore important that patients have access to rapid assessment for rapidly growing tumors.

**121.2.3.2 Overlap with Mosaic NF2 in Sporadic Cases.** In the absence of a clear family history, the clinical dilemma is distinguishing schwannomatosis from mosaic NF2 (284). The appearance of the tumors is clinically and radiologically the same as in NF2. The more severe pain seen in schwannomatosis nerve lesions is a helpful clinical clue. Peripheral nerve lesions in NF2 are often only painful on pressure. Clinical assessment to exclude any signs of NF2 is essential when a diagnosis of schwannomatosis is considered and should include a thorough cutaneous and eye examination for signs of NF2 and full MRI neuraxis imaging. Molecular analysis is also available now, as discussed below. After tumor analysis, Smith et al. (292) found four of nine (40%) of their sporadic cases with multiple schwannomas had mosaic NF2.

**121.2.3.3 Risk of Malignant Rhabdoid Tumors?** The identification of *SMARCB1* mutations in some schwannomatosis patients raised the question as to whether there was also a risk of MRTs. This is because germline *SMARCB1* mutations have also been found in the extremely rare families with a predisposition to these tumors (286,288). Rhabdoid tumors are aggressive pediatric malignancies with a poor prognosis that develop in infancy and early childhood. They most commonly occur in the brain (where they are called atypical teratoid/rhabdoid tumors), kidney, and soft tissue.

At the cellular level, the tumors result from biallelic *SMARCB1* inactivation, in the majority of cases due to somatic mutation. Familial cases have been reported with germline mutations. Eaton et al. (Eaton 2011)

found germline mutations in 35 of 100 cases with MRT. In 22 of 35 cases parental samples were available and in 7 of 22 of these cases one parent had the mutation. In a further two families with affected siblings, parental analysis was normal, demonstrating germline mosaicism. Two of the seven parents with mutations had one or more schwannomas and a positive family history of schwannomas; one of these families has been reported previously (Swensen 2009). A third reported family was ascertained through the mother who had sarcomatous change in a schwannoma (289). A son had died of cerebellar rhabdoid tumor 6 years earlier. During the mother's genetic counseling, a younger son developed a cerebellar rhabdoid tumor. In the Eaton et al. (286) series, three of seven parents with mutations had no MRT or schwannomas and one an ill-defined CNS lesion not suggestive of MRT. These findings demonstrate nonpenetrance for *SMARCB1* in MRT families.

The emerging literature suggests that *SMARCB1* immunohistochemistry may contribute in assessing cases. The majority of schwannomas in schwannomatosis and NF2 show a mosaic pattern of *SMARCB1* staining (294). In this study no correlation was available with germline *SMARCB1* status. In MRT families the tumors show complete loss of *SMARCB1* staining. In one of the three families with both schwannomas and MRT, Carter et al. (289) reported that both the malignant peripheral nerve tumor and schwannomas showed complete loss of *SMARCB1*. Furthermore, all but one of the schwannomas studied were neuroblastoma-like schwannomas, a very rare variant.

**121.2.3.4 Diagnostic Criteria.** MacCollin and colleagues (284) have proposed diagnostic criteria. Definite schwannomatosis would be diagnosed in an individual at least 30 years of age with two or more nonintra-dermal schwannomas (at least one histologically confirmed), no evidence of vestibular schwannoma by high-quality MRI, and no known NF2 mutation. The diagnosis would also be made on pathologic confirmation of a schwannoma in a first-degree relative of an individual known to be affected. Criteria were also proposed for possible diagnosis in individuals under age 30 who fulfill these criteria but may be too young to manifest vestibular schwannoma, as well as in older individuals who have no symptoms of vestibular tumor but have not had imaging studies. A segmental form was proposed in which the features are limited to one limb or five or fewer contiguous spinal segments.

Smith et al. (292) have recently reported two cases with a clinical diagnosis of schwannomatosis, both of whom had neither NF2 nor *SMARCB1* mutations on testing. They did, however, have unilateral vestibular schwannomas and in one case, mutation analysis on tumors was compatible with schwannomatosis rather than NF2 (see below). They also reported a family with an *SMARCB1* mutation, in whom the proband had previously been diagnosed with NF2 after presenting with

spinal schwannomas and was found to have a right cerebellopontine angle lesion that was thought to be a vestibular schwannoma. Radiological review suggested that the tumor was in fact on the jugular nerve. Smith et al. (292) concluded that vestibular schwannomas may rarely occur in schwannomatosis and highlight the importance of expert radiological review of cerebellopontine angle lesions to determine the cranial nerve on which the schwannoma(s) has arisen.

**121.2.3.5 Genetics.** The majority of cases of schwannomatosis are sporadic, with some patients having localized lesions suggestive of mosaicism. The risk to offspring of sporadic cases is much less than 50%; MacCollin et al. (284) suggest an empirical risk of less than 15%. In familial cases inheritance is dominant but expression is variable and incomplete penetrance is recorded (284). Germline mosaicism of an *SMARCB1* mutation in schwannomatosis has been reported (295).

**121.2.3.6 Pathogenesis.** The genetic mechanisms underlying schwannomatosis are gradually being elucidated. The gene has been localized to chromosome 22 proximal to NF2 and mutations in the *SMARCB1* tumor suppressor gene were first reported in 2007 (285). Combining their own and other published series, Smith et al. reported that in familial schwannomatosis cases 45% (22 of 49) have *SMARCB1* mutations but only 7% (14 of 190) of sporadic cases have these mutations (292,296–299). Tumor analysis has shown a complex mechanism of tumorigenesis in schwannomatosis, which requires somatic mutation in both copies of the NF2 gene as well as in *SMARCB1* (Hadfield 2008; Sestini 2008). The majority of reported cases/families with *SMARCB1* mutations have just had schwannomas. As discussed above, there are families with both schwannomas and MRTs reported. Two schwannomatosis families with meningiomas have also been shown to have mutations (290,291). *SMARCB1* encodes a core component of the SW1/hSNF chromatin remodeling complex, which regulates expression of around 5% of genes across the genome (reviewed by Reisman et al. (300)).

**121.2.3.7 Genotype–Phenotype Correlation.** The reasons that mutations in the same gene cause schwannomatosis in some cases but MRT in others, with little overlap, are emerging. Studies to date show that the majority of mutations in schwannomatosis-only families are nontruncating, which is in marked contrast to MRT, where the majority are truncating mutations or deletions or duplications (288,292). It has been proposed that there is an early developmental window in which a mutation carrier is predisposed to MRT, and those that survive may have a later predisposition to schwannomas. It seems likely that different mutations confer different risks of the two tumors. Many schwannomatosis mutations may be hypomorphic, conferring a very low risk of MRT but resulting in multiple schwannomas later in life.

**121.2.3.8 Genetic Counseling and Genetic Testing.** Our knowledge of schwannomatosis is increasing

rapidly. It is therefore essential that up to date information is used when counseling families. Although inheritance is dominant in familial cases, there is well-recorded nonpenetrance. With regard to molecular testing at the current time, if the clinical picture is very typical of schwannomatosis (e.g. family history and no vestibular schwannomas, or schwannomas and meningiomas or MRT in family members) direct *SMARCB1* testing is appropriate.

In sporadic cases, prior to genetic testing it is essential to check that a full workup to exclude NF2 has been done. If tumor tissue is available from two or more tumors it is then usually more helpful to proceed to tumor mutation analysis of *NF2* and *SMARCB1*. In mosaic NF2 each separate tumor will share one mutation in common, whereas in schwannomatosis the *NF2* mutations are different in each tumor. If no tumor is available then *NF2* and *SMARCB1* analysis should be done. This will be normal in the majority of cases, and the empirical risk to children is much reduced.

#### 121.2.4 Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is the now preferred name for the condition previously known as tuberous sclerosis. The addition of the term complex emphasizes the multisystem involvement and variable expression of the disease. In the older literature, it is often referred to as Bournville disease, giving eponymous credit to Bournville (301), who gave the first detailed report of the neurologic symptoms and gross cerebral pathology of TSC. Bournville coined the term tuberous sclerosis of the cerebral convolutions to describe the brain of one of his cases because its nodular appearance resembled tubers. Another old and unfortunate term for TSC, used mainly in the United Kingdom, was epiloia, reflecting the combination of epilepsy with anopia, or mindlessness.

TSC was previously considered to be relatively rare. As more mildly affected cases have been diagnosed, estimates of prevalence/incidence have increased. In a UK study, taking account of underascertainment, O'Callaghan and associates (302) reported a prevalence of 1 in 12,500, whereas a study by Devlin et al. calculated a prevalence in Ireland of 1 in 24,956 (303). The birth incidence may be as high as 1 in 6000 (304,305).

**121.2.4.1 Clinical Features.** The clinical features of TSC involve several body systems and develop at different ages (Table 121-4). This means that, as in NF1, the assessments should vary according to the age of the individual. For many years, it was believed that the triad of features identified by Vogt (306) of mental retardation, epilepsy, and adenoma sebaceum had to be present for the diagnosis of TSC; however, as this triad is only present in approximately 30% of cases, many patients were undiagnosed.

##### 121.2.4.2 Cutaneous Features.

**121.2.4.2.1 Hypomelanotic Macules.** Hypomelanotic macules are the first cutaneous feature to become

obvious; they are present from birth or develop during early childhood, and may increase in number during childhood (307). In the majority of patients, the macules are easily visualized under normal lighting. There may be between 1 and 100 hypopigmented patches, present in 80–90% of patients (308–310). They are usually easily seen in room light, but the Wood's lamp may help to visualize hypopigmented macules if they are not seen with room lighting. Fitzpatrick and colleagues (311) described three main types of hypopigmented lesions in TSC:

- (1) The type seen most frequently has a rounded shape like a thumbprint, 0.5–2 cm in diameter.
- (2) The second type has a lancinate-ovate shape, 1–12 cm in length, said to resemble the leaf of a mountain ash tree (and may be known as an “ash-leaf spot”).
- (3) The least frequent type consists of patches of skin containing multiple areas of small (1–3 mm) hypopigmented lesions (“confetti” lesions).

Hypopigmentation in TSC can also involve the hair of the scalp (poliosis), eyebrows, and eyelashes. Caution must be exercised when hypopigmented patches are found as the only feature in childhood, as 2 or 3 per 1000 normal neonates also have them (312,313).

**121.2.4.2.2 Facial Angiofibromas (“Adenoma Sebaceum”).** Facial angiofibromas (Figure 121-5) are present in 80–90% of older TSC patients (308,310). They begin to develop from around the age of 5 years to puberty, when they often become more numerous and prominent. The inaccurate name of adenoma sebaceum derives from the fact that there are a large number of sebaceous glands in the facial area where these lesions develop. Histologically, the angiofibroma is a hamartoma of dermal connective tissue and blood vessels. Typically red or pink nodular lesions appear distributed symmetrically on both sides of the face. They often involve the whole nose, spread onto the cheeks (particularly the nasolabial folds), and may also occur on the chin. These lesions can present a considerable cosmetic burden. A variety of options are available to remove these lesions, including shave excision, cryosurgery, desiccation, dermabrasion, and carbon and argon laser (308,309). The use of medications to treat angiofibroma and other skin lesions will be described later in this section.

**121.2.4.2.3 Shagreen Patch.** Shagreen patches (Figure 121-5) usually develop in later childhood. Webb and colleagues (308) found 41% of patients to have these patches and Chopra reported a frequency of 65% (310). A shagreen patch appears as a slightly elevated, roughened patch of skin, yellowish brown or pink in color, with the texture of pigskin or orange peel. They are firm or rubbery in consistency and vary in size from a few millimeters to 10 cm or more. They are usually found on the dorsal surface of the trunk, particularly in the thoracolumbar region, but may occur in the dorsal cervical area. They rarely cross the midline and are rarely seen on the ventral aspect of the trunk.

**FIGURE 121-5** Tuberous sclerosis complex. (A) Facial angiofibromas. (B) Periungual fibroma. (C) Dental pits. (D) Shagreen patch.

**121.2.4.2.4 Forehead Plaque.** Forehead plaques often develop in early childhood and may grow slowly before puberty or involute at an older age. They appear as raised soft patches of skin and can be red, yellow, or flesh-colored. They were present in 26% of cases in the Osborne et al. series (304).

**121.2.4.2.5 Ungual Fibromas.** Ungual fibromas usually develop in adult life (Figure 121-5), with a reported frequency up to 88% (308). The lesions may be peri- or subungual and appear as dull red or flesh-colored papules or nodules. The periungual lesion is a fibrous nodule arising from the unguinal groove of fingers or toes. It grows on the nail plane in the same direction as the nail and may be 1 mm or more in diameter. The subungual fibroma grows under the free edge of the nail as a slightly raised nodular tumor, which lifts the nail off the nail bed. Some lesions can lead to longitudinal splitting of the nail. Ungual fibromas are found more often on the toes than on the fingers and are more common in females.

**121.2.4.3 Oral Findings.** Pitted enamel hypoplasia (Figure 121-5) has been found in both adults and children with TSC (314), but is never symptomatic. Sampson's group found no pits in deciduous teeth, but in the permanent teeth of TSC patients they found pits easily visible to the naked eye in 48% of patients, compared

with 5 of 563 controls (0.88%) (314). Sparling et al. reported enamel pits in 97% of 56 patients (315). Some investigators have used techniques that allow the detection of microscopic pits; although microscopic pits are found in a higher proportion of TSC patients, they are also found in more of the general population. Sparling et al. (315) also noted fibromas in the oral cavity in 69% of their patients, not only on the gingiva but also on the tongue, palate, and buccal surfaces.

#### **121.2.4.4 Central Nervous System Involvement.**

**121.2.4.4.1 Pathology.** The two characteristic features of CNS involvement in TSC are the cortical tubers and subependymal nodules. The tubers are focal lesions that occur predominantly at the gray–white matter interface. Macroscopically they are paler and firmer than the rest of the brain, and microscopically they show loss of normal cortical cytoarchitecture with occurrence of abnormal neurons and glial cells. The neurons may be gigantic and the glial cells may also be enlarged and morphologically abnormal (316,317). The cortical tubers disrupt and displace normal cortical architecture, and their number or location roughly correlate with the severity of the seizures and mental retardation in TSC (318,319). They are present in the majority of patients, being found in 95% in one series (320), and are best seen by MRI

using the FLAIR sequence (321). White matter lesions, consisting of radial bands, are best visualized with T1 spin echo with magnetization transfer contrast medium pulse on resonance (T1-SE/MTC) (321).

The subependymal nodules are found lining the third ventricle. They are composed of large irregular cells that are more densely aggregated and more uniform in appearance than cortical tubers. In the Braffman et al. series (320), 95% of the patients had subependymal nodules on MRI. Some of the nodules grow larger than 3 cm in diameter and these larger lesions are often referred to as subependymal giant cell astrocytomas (SEGAs). O'Callaghan et al. (322) found SEGAs measuring at least 1 cm in 17% of 41 patients and symptomatic lesions in 10 of 149 patients. These lesions can grow (323) and obstruct the foramen of Monro, leading to hydrocephalus (324). The average age of presentation of these tumors is 13 (range, 1–31 years) (325).

**121.2.4.4.2 Epilepsy.** In the UK population-based survey (326), 78% of individuals (102 of 131) had seizures; 69% of those had seizures in the first year of life and in 4% the seizures began in adulthood. About 50% of patients presenting with infantile spasms, with the characteristic electroencephalographic (EEG) finding of hypsarrhythmia, will turn out to have TSC. In the Webb et al. survey (326), half the TSC patients presented with a variety of other forms of seizure (partial, tonic-clonic, myoclonic, and febrile seizures). Seizure control was poor in 25% of patients in this series (defined as daily or weekly seizures). Resistant seizures (defined as more than one per year despite treatment) were more common following infantile spasms and myoclonic seizures and when onset of seizures occurred under 2 years of age. Males were three times more likely to have weekly or daily seizures resistant to treatment. Chu-Shore et al. (327) studied the natural history of seizures in 291 patients. A history of seizure was found in 85.2% and infantile spasms in 37.8%; multiple seizure types were seen in 54.1%. Seizures began in the first year of life in 63.2% and 12% of adults had the first seizure in adulthood. Patients with infantile spasms have the highest risk of intellectual disability (328) and may benefit from treatment with vigabatrin (328–331).

**121.2.4.4.3 Learning Disability and Behavior Disorders.** The level of intellectual disability in TSC is much more severe than that seen in NF1; 53% of individuals in the Webb and colleagues survey (326) had learning disability, 59 of these 68 patients (87%) required at least some supervision of daily living, 65% had little or no language, and 63% needed daily help with feeding, dressing, or toileting. Winterkorn et al. (332) found normal IQs in 57% of 107 patients.

Various studies have shown that all TSC patients with intellectual involvement have had seizures at some stage (326,333). The converse is not true, and in the Webb series 31% of patients with epilepsy had a normal intellect (326). Prognosis for intellectual outcome is worse

with an earlier onset of seizures and the occurrence of infantile spasms (332) (see above). Intellectual disability is also associated with the type of seizure and the level of seizure control (331,334). Behavior disorders, including attention deficit disorder, are a significant problem in TSC; 20–50% of the children show autistic features (335–338). Adults have an increased frequency of psychiatric disorders, including interpersonal sensitivity, psychoticism, depression, and obsessive-compulsive symptoms (339), as well as sleep disturbance (340).

**121.2.4.5 Renal Involvement.** Two characteristic renal lesions are seen in TSC: angiomyolipomas and renal cysts. An individual patient may have one or both of these lesions or be unaffected (341,342). They are usually multiple and bilateral; most are asymptomatic. There may also be a slightly increased frequency of renal cell carcinoma (343,344).

Angiomyolipomas were found in 67% of reviewed autopsy cases when kidney examination was specifically mentioned (345) and in 49% of patients in a clinical study (341). They were found more frequently in older patients—only 8% of children aged 5 years or younger at autopsy had them, compared with 93% of those older than 10 years. In a population-based study of renal disease in the United Kingdom (346), 6 of 131 patients (4.6%) had symptomatic renal angiomyolipomas. They had presented because of abdominal pain with or without hematuria, and a renal mass was then found on examination. In the same study, a subpopulation of 21 patients had renal ultrasound; two of these patients were known to have symptomatic angiomyolipoma, and ultrasound scanning detected a further five lesions, giving an overall frequency of 33%. The lesions were more frequent in females (45%) than in males (20%). Similarly, most of the patients in the study by Cook et al. (341) were asymptomatic, with hematuria, abdominal pain, and urinary tract infection being the most common clinical problems in symptomatic individuals. Rakowski et al. (347) reported renal lesions in 96 of 167 patients, of which 85.4% were angiomyolipomas. Hemorrhage occurred in six patients. Conservative management and monitoring are appropriate for most patients (348); symptomatic tumors can be treated by embolization, radio-frequency ablation, or partial nephrectomy (349–354) and may also respond to medical therapy (see below).

Renal cysts in TSC can be few and asymptomatic or numerous and macroscopically similar to adult polycystic kidney disease (345). The basis for development of multiple renal cysts appears to be codeletion of the *TSC2* and *PKD1* genes on chromosome 16 (355). Cook and associates (341) found renal cysts in 32% of patients with TSC and Rakowski et al. (347) reported cysts in 44.8% of the patients who had renal lesions. In the UK population-based study (346), 2 of 131 patients (1.5%) had polycystic kidney disease; both presented in early childhood with abdominal masses, one child also had hematuria, and both were hypertensive. None of the

cases in the UK population study had renal carcinoma, whereas Rakowski et al. (347) reported renal cell carcinoma in 4 of 167 patients; the overall risk in the TSC population appears to be small. An increased relative risk is suggested, however, by the fact that reported cases of renal carcinoma in TSC have occurred at a young age and the cancers have been multiple and bilateral in several patients (343,345), although a meta-analysis by Tello and coworkers (344) did not reveal an increased risk of renal cell carcinoma in association with TSC.

**121.2.4.6 Cardiac Rhabdomyomas.** On echocardiography, 50% of children with TSC are found to have cardiac rhabdomyomas (356). These lesions tend to be multiple, and their size and number decrease with age (357). Most lesions are asymptomatic. Those that will cause problems tend to present in infancy with heart failure (either due to outflow obstruction or because of replacement of normal myocardium with hamartoma), or arrhythmias (typically preexcitation syndromes) (358). In the UK population-based study, Webb et al. (326) identified only 2 of 131 living patients (1.5%) who had had symptomatic rhabdomyomas in early childhood. Cardiac tumors have been used as a basis of prenatal diagnosis of TSC (359,360) and are often the first presenting sign in a newborn or a young child (361,362).

**121.2.4.7 Ophthalmic Features.** The ophthalmic features of TSC are usually asymptomatic. Approximately half (68 of 139) of the patients in the Mayo Clinic series (363) had retinal hamartomas. There were three types of lesions: (1) relatively flat with a smooth surface and round or oval with indistinct boundaries, salmon to salmon-gray color, present in 28% of patients; (2) classical, relatively easily seen retinal astrocytomas, elevated multinodular lesions that resemble mulberries and are calcified, present in 24% of patients; and (3) transitional in appearance between the other two kinds, present in 5.7% of patients. The retinal hamartomas in TSC rarely cause significant visual problems (364). In addition to the hamartomas, some patients also show pigmentary lesions of the retina; 13% of the patients in the Mayo Clinic series had pigmentary abnormalities, usually in the form of depigmented patches (363).

**121.2.4.8 Other Lesions.** TSC can affect virtually any part of the body except perhaps the skeletal muscle. Apart from the disease features already discussed, the only other lesions that caused symptoms in the UK population-based series (326) were pulmonary involvement and colonic angiodysplasia, both occurring in 1 of 131 cases (0.8%).

Pulmonary involvement in TSC is five times more common in girls and can present with respiratory failure, hemoptysis, and/or spontaneous pneumothorax. The characteristic pathology is lymphangioleiomyomatosis (LAM). Symptoms seldom occur before the third or fourth decade (365–367), but the prognosis is poor once severe pulmonary involvement has been demonstrated. LAM tends to occur in association with

renal angiomyolipoma and may represent a metastatic spread of the renal lesion (368). The tumors are estrogen sensitive, possibly explaining their female predilection. Subclinical LAM is found in a high proportion of women with TSC if they are imaged with high-resolution CT (369).

Microhamartomatous rectal polyps were found on rectal biopsy in 14 of the 18 patients (78%) examined by Gould (370). The patients studied were intellectually impaired but, as far as could be ascertained, had no gastrointestinal symptomatology.

Asymptomatic liver hamartomas were found in 23.5% of children examined by abdominal ultrasound, more often in girls than boys (ratio 5:1) (371). Their incidence increased with age, reaching 45% in children over the age of 10. The lesions are presumed to be angiomyolipomas. Black et al. (372) reported angiomyolipomas, cysts, and other lesions in 30% of 205 patients, but none had clinical symptoms because of their lesions.

**121.2.4.9 Diagnostic Criteria and Differential Diagnosis.** The diagnosis of TSC is straightforward when children present with epilepsy and are found to have characteristic signs on cutaneous examination and neuroimaging. Not all patients with TSC present in this manner, however, and difficulties arise because of the diverse phenotypic expression and variation in age of onset of disease features. Difficulties in diagnosis have led to the evolution of detailed diagnostic criteria over the past two decades (373,374). The clinical features of TSC are divided into major and minor features. Definite diagnosis requires either two major features or one major feature with two minor features. Probable TSC results when one major feature and one minor feature are present. The occurrence of either one major feature or two or more minor features raises suspicion of possible TSC, but does not establish the diagnosis.

- (1) Major features: facial angiofibromas or forehead plaque, nontraumatic ungual or periungual fibroma, hypomelanotic macules (at least 3), shagreen patch, multiple retinal nodular hamartomas, cortical tuber, subependymal nodule, SEGA, cardiac rhabdomyoma (single or multiple), lymphangioleiomyomatosis, renal angiomyolipoma.
- (2) Minor features: multiple pits in dental enamel, hamartomatous rectal polyps, bone cysts, cerebral white matter radial migration lines, gingival fibromas, non-renal hamartoma, retinal achromic patch, “confetti” skin lesions, multiple renal cysts.

If cortical dysplasia and white matter migration tracts occur together, they should be counted as only a single feature; if lymphangioleiomyomatosis and renal angiomyolipomas are both present, one other feature of TSC should be present before a diagnosis is established.

In terms of differential diagnosis, there is no disease that has close phenotypic overlap with TSC; we do, however, see patients with misdiagnosis of specific disease

features—for example, early facial angiofibromas are often misdiagnosed as acne. The most difficult issues in relation to the diagnosis of TSC are in the interpretation of the finding of isolated disease features in individual patients.

**121.2.4.10 Natural History.** TSC exhibits a wide range of variable expressivity. Diagnosis may be established at birth, or even prenatally, or may be delayed until well into adulthood. Some adults learn of their own diagnosis when the condition is diagnosed in a child. Morbidity and mortality in TSC are dictated by the presence or absence of the various features of the disease and their severity. In the UK population-based study, Webb and colleagues (326) found the major cause of morbidity to be epilepsy, as discussed earlier. Shepherd and Gomez (343) studied the causes of death in the Mayo Clinic cohort: 49 of a cohort of 355 patients had died; in 40 of 49 the cause was related to TSC. The most common cause of death was renal disease, occurring in 11 of 49 patients, all of whom were more than 10 years of age. The frequency of renal death increased with age. Seven patients died of renal failure, two of bleeding angiomyolipomas, and two of renal cell carcinoma. The next most frequent cause of death was SEGAs in 10 patients; death was due to the tumor in 6 cases and related to treatment in 4 cases. These tumors occurred most frequently in the 10- to 19-year-old group. Four patients died from lymphangio-myomatosis of the lung (three female, one male), all of whom were older than 40 years. A total of 13 patients with severe mental handicap died at different ages, with the cause of death listed as status epilepticus in nine and bronchopneumonia in four. The final two patients died of cardiovascular causes in early childhood, one of multiple cardiac rhabdomyomas at 3 days and another of rupture of thoracic aortic aneurysm at 3 years.

**121.2.4.11 Genetics.** TSC follows autosomal dominant inheritance with variable expression both within and between families. Between 50% and 75% of all cases are sporadic, and the mutation rate is in the about  $2.5 \times 10^{-5}$  per generation (304). Sampson et al. (375) found no significant parental age effect for the new mutations. Because of the disease-associated morbidity, large families with TSC are uncommon, but within those studied there has been no evidence of nonpenetrance. Germline mosaicism has been demonstrated, as has somatic mosaicism in instances in which a parent shows only minimal clinical signs of the disorder (376).

**121.2.4.12 Pathogenesis.** Before molecular genetic analysis of TSC, there had been no real insights into the pathogenesis of the disease. The nature of the lesions suggests that a tumor suppressor or “two-hit” model would be a reasonable assumption. Genetic linkage studies indicated the existence of two distinct TSC loci, one on chromosome 9 (377) designated *TSC1* and the other on chromosome 16 (378) designated *TSC2*. *TSC1* was cloned by van Sleight et al. (379). The gene is located at 9q34 and encodes a protein of 1164 amino acid residues referred to as hamartin. *TSC2* is located at

16p13 and encodes a protein of 1784 amino acid residues, referred to as tuberin (380). Tuberin and hamartin are both expressed in neurons and interact with one another (381,382), suggesting that they act together in the same cellular pathway. Tuberin shows a region of homology with a GAP domain and functions as a negative regulator of the Ras-family GTPase Rheb, which in turn is a positive regulator of mTOR (383,384). Loss of tuberin GAP activity leads to high levels of Rheb-GTP, activation of mTOR, and consequent inhibition of S6K and activation of 4EBP1, two proteins involved in the control of ribosome function (385) and protein biosynthesis. Tuberin thereby functions in the Akt/PI3 kinase pathway, which regulates cell growth in situations of nutrient deprivation.

Support for a tumor suppressor model comes from the study of loss of heterozygosity for the *TSC1* and *TSC2* regions in various hamartomas from TSC patients (386–391), and also by the finding that rat *TSC2* is mutated in the Ecker rat, which manifests hereditary renal cell carcinoma (392). Activation of mTOR has been shown in some tubers (393), compatible with effects of loss of Rheb inhibition by tuberin. Loss of heterozygosity or small point mutations have not been found in most tubers (390,394), but Crino et al. (395) did identify biallelic mutations in giant cells microdissected from tubers. This suggests that tubers arise from interactions between cells with biallelic mutations and surrounding haploinsufficient cells.

**121.2.4.13 Genotype–Phenotype Correlation.** Mutations are widely distributed across *TSC1* and *TSC2*, with most leading to lack of expression of the respective gene products (396,397), although some missense mutations have been identified (398). The detection rate in 325 patients in the study of Au et al. (397) was 72% in de novo cases and 77% in familial cases. Kozlowski et al. (399) found large deletions in 0.5% of patients with *TSC1* mutation and 6% of those with *TSC2* mutation. Somatic mosaicism accounts for some individuals with undetected mutations, but so far has not been detected in all (400). Although phenotypes may vary even within a family (401), it appears that phenotypic effects may on average be milder for patients with *TSC1* rather than *TSC2* mutations (397). Analysis of deletions of the *TSC2* locus has identified one specific correlation to date. As we have discussed, severe polycystic kidney disease, presenting in early childhood, is a rare manifestation of TSC. Brook-Carter et al. (402) studied six sporadic patients with this TSC phenotype and found that all had large deletions disrupting both *TSC2* and the nearby polycystic kidney disease gene *PKD1*. Disruption of *PKD1* was not found in other TSC patients with less-severe cystic involvement, indicating that renal cysts in TSC can arise by at least two different mechanisms.

#### **121.2.4.14 Management/Treatment.**

**121.2.4.14.1 Affected Individuals.** In the past, the management of affected individuals with TSC was dictated by the problems caused by the condition; many

patients were under the care of pediatric and adult neurologists because of their epilepsy. As there are many possible manifestations of the disease, it is advisable for all children with TSC to be reviewed at least annually, and there may be a role for multidisciplinary TSC clinics. Adults with ongoing problems will also require regular review.

Recommendations for screening were proposed by the NIH Consensus Development Conference (373), and evidence-based guidelines have also been proposed (403). Brain MRI was recommended by the NIH panel every 1–3 years in children, with a reduction in frequency of monitoring in adults. Renal imaging by ultrasound, CT, or MRI was recommended every 1–3 years in adults. Children should be monitored closely for development (404). Other studies, such as EEG, electrocardiography or echocardiography, dermatologic screening, and pulmonary CT would be performed as clinically indicated.

The discovery of the role of dysregulation of mTOR in the pathogenesis of lesions associated with TSC has suggested the possibility of treatment with drugs that inhibit mTOR activity. This has been borne out in preclinical studies (405,406) and early clinical studies showed regression of SEGAs (407) and renal angiomyolipomas (408). Bissler et al. (409) conducted an open-label trial in 25 patients with renal angiomyolipomas. After 12 months of therapy, the mean volume decreased to approximately 53% of baseline, but regrowth occurred to a mean volume of approximately 86% of baseline; 5 of 20 patients who were evaluated at 24 months had a 30% or greater persistent reduction in volume of angiomyolipomas. Patients with LAM experienced an improvement of pulmonary function while on treatment. Krueger et al. (410) conducted an open-label trial of the mTOR inhibitor everolimus in 28 children aged 3 years or older with SEGAs. At least a 30% reduction in size occurred in 21 patients by 6 months of therapy. An improvement in seizure control was also noted. Similar results were reported by Curran (411). Dabora et al. (412) noted regression of angiomyolipomas of the kidney or liver as well as SEGAs in adults treated with sirolimus in a phase 2 trial. Either oral or topical rapamycin has been reported to result in improvement in angiofibroma (413–416). Everolimus has now been approved by the Food and Drug Administration in the United States for treatment of symptomatic SEGAs and clinical trials are ongoing to assess the effectiveness in the treatment of other TSC lesions. Side effects of mTOR inhibitors include oral ulcers, increased susceptibility to infection, hypercholesterolemia and hyperlipidemia, and, in rare cases, pneumonitis.

**121.2.4.14.2 Investigation of Relatives of Apparently Isolated Cases.** The role of the clinical geneticist in TSC families is usually in the investigation of family members of a proband. Very occasionally it becomes obvious during the clinic assessment that one of the parents has mild undiagnosed TSC, but more often the proband will be an apparently isolated case. Clinical evaluation

of parents should include fundoscopic examination, brain MRI, renal imaging, and dermatologic screening as part of the evaluation of asymptomatic relatives. Even when both parents are apparently unaffected, there is a small but significant risk of germline mosaicism. Clinical studies have shown the risk to lie between 1% and 6% (375,417,418). Prenatal diagnosis can be achieved in families in which the mutation has been identified. It has also been accomplished using ultrasound to detect cardiac rhabdomyoma (419) or MRI to detect subependymal nodules (420,421).

**121.2.4.15 Molecular Genetic Testing.** Molecular genetic testing is possible, although complicated by the fact that two distinct genes must be tested, with a wide diversity of possible mutations in either gene (422,423). Testing may be helpful to corroborate the diagnosis in cases of uncertainty or for prenatal testing and may reveal the presence of a gene mutation in advance of clinical signs (424).

## 121.2.5 von Hippel–Lindau Disease

VHL disease is the third most frequent phakomatosis, with a disease prevalence in the range of 1 in 40,000–53,000 (425,426). Maher and colleagues (425) estimated the birth incidence to be 1 in 36,000 live births. VHL is different from the other phakomatoses in that there is no cutaneous involvement, but there is multiple system involvement of the eye, CNS, pancreas, adrenal gland, kidney, and epididymis. VHL's eponymous name originates from the contributions made by Eugene von Hippel (427) and Arvid Lindau (428). von Hippel studied the retinal lesions, concluded they were hemangioblastomas, and coined the term angiomatosis retinae. Lindau, in a study of cerebellar cysts, concluded that most are associated with an angio-blastic neural tumor often with hemangioblastomas elsewhere in the CNS or retina, or renal cysts. van der Hoeve (2) first used the term VHL disease to describe cases with both angiomatosis retinae and cerebellar hemangioblastomas in his Doyne Memorial lecture. We briefly discuss the different disease features of VHL, its age of presentation, and family management.

**121.2.5.1 Clinical Features.** The frequency and age of presentation of the disease features are shown in Table 121-5 (429,430). Approximately 8% of patients will have only one disease manifestation (426,430).

**121.2.5.2 Retinal Angiomas (Hemangioblastomas).** Although the retinal lesions in VHL are hemangioblastomas, they are referred to as retinal angiomas in the ophthalmology literature. All patients with multiple retinal hemangioblastomas have VHL disease by definition. Isolated lesions can occur in the general population. Retinal hemangioblastomas are the most common presenting feature of VHL disease and are multiple and bilateral in about one half of the cases (431). In the study by Maher et al. (430), they were present in 89 of 152 cases (59%), and in a large literature review (432), in

317 of 554 cases (57%). Retinal hemangioblastomas have rarely been reported in early childhood and in the ninth decade of life (433), but the usual age of presentation is in the early twenties (431). In the Maher series (430), 54 of 89 patients had symptomatic retinal lesions that presented at a mean age of 24.5 years (range, 4–46 years) and the remaining 35 were asymptomatic, with a mean age of detection of 27 years (range, 7–68 years).

The typical direct ophthalmoscopic appearance of a retinal hemangioblastoma is that of a dilated artery

leading from the disk to a peripheral tumor with an engorged vein. Indirect ophthalmoscopy is usually needed to detect smaller lesions at an early stage, when they appear similar to diabetic microaneurysms but lie peripherally between large arterial and venous trunks (431,434). Screening for the retinal manifestations of VHL consists of direct ophthalmoscopy through dilated pupils as a minimum; indirect ophthalmoscopy is more sensitive for smaller lesions.

Small peripheral retinal lesions are usually asymptomatic, but if they enlarge or are located centrally, they can cause profound visual loss. Arteriovenous shunting and leaky capillaries lead to exudation of fluid, and hemorrhage can result in a number of complications, including retinal detachment, macular edema, and glaucoma. The cumulative risk of visual loss from retinal angiomas was estimated at 35% in all gene carriers and 55% in patients with retinal angiomas at age 50 years (434). Management is therefore directed toward detecting asymptomatic lesions to prevent complications. Most angiomas respond well to laser photocoagulation or cryotherapy. Optic disk lesions are difficult as there is a risk of nerve damage with treatment. They are therefore usually kept under surveillance unless there is evidence of progression. Antiangiogenic therapy may be an option for lesions where conventional therapy is contraindicated (435,436).

**121.2.5.3 Central Nervous System Hemangioblastomas.** CNS hemangioblastomas develop most commonly in the cerebellum (59% of VHL cases) (Figure 121-6), but are also found in the spinal cord (13%), brain stem (4%), or elsewhere in the CNS (less than 1% of cases) (429,437). All cases with multiple CNS hemangioblastomas have VHL disease. Huson et al. (438) found that 40% of a series of patients with cerebellar hemangioblastomas had VHL disease; they were distinguished from isolated lesions by a younger mean age of

<b>TABLE 121-5 von Hippel–Lindau Disease: Clinical Features and Age at Presentation</b>		
<b>Feature</b>	<b>Frequency (%)</b>	<b>Mean Age at Presentation</b>
<b>Hemangioblastoma</b>

NA, data not available; NA\*, usually asymptomatic; Asymptomatic, detected through screening as opposed to presenting with symptoms.

Data from Maher and colleagues (430) and Choyke and coworkers (429).

**FIGURE 121-6** von Hippel–Lindau imaging. (A) MRI appearance of cerebellar haemangioblastoma in sagittal section. (B) Abdominal CT showing an asymptomatic renal carcinoma detected on initial screening of a 52-year-old man who had had three cerebellar hemangioblastomas removed.

presentation—the isolated cases presented at a mean age of 53 years (range 38–75), but in VHL they presented at 28 years (range 10–49 years). Spinal hemangioblastomas are associated with VHL in 80% of cases (429). The mean age of presentation of cerebellar hemangioblastoma in VHL in Maher and colleagues' series (430) was 29 years (range 13–61 years).

The signs and symptoms related to the CNS hemangioblastomas are related to their location. In addition to pressure-related symptoms, there is also a risk of hemorrhage. Spontaneous hemorrhage without prior symptomatology is unusual and occurred in only 1 of 20 of the lesions in the Cardiff series (438). Gadolinium-enhanced MRI is the most sensitive method for detecting these lesions. With screening MRI now being used in asymptomatic family members, small haemangioblastomas that remain static for some years are being detected. Removal of asymptomatic lesions is not usually indicated (439,440). The outcome of surgical resection is usually good in cerebellar lesions, but surgery can be more difficult elsewhere in the CNS and in cases with multiple or recurrent lesions (439,441). Stereotactic radiotherapy may be an alternative to conventional surgery in noncystic small lesions particularly in difficult locations, although complications can occur (439,441).

**121.2.5.4 Renal Involvement.** Patients with VHL can have both cysts and renal carcinoma. The cysts are usually multiple but are rarely symptomatic or affect renal function. Their lining epithelium may be dysplastic or show carcinoma in situ, which may then give rise to renal cell carcinoma. The carcinomas are clear cell in type. Examination of kidneys removed from VHL patients shows large numbers of microscopic tumor foci in apparently normal parenchyma; this explains the high risk of multiple and bilateral carcinoma in VHL (442).

Renal carcinoma is a major cause of death in VHL and screening programs are geared toward early detection and treatment of small tumors (435). The risk of renal carcinoma varies in different subtypes (see Section 121.2.5.11). In the most common forms (type 1 and 2B) the lifetime risk is approximately 70% (443). The mean age of symptomatic diagnosis is around 40 years. In screened patients asymptomatic lesions are detected much earlier, but rarely before age 16 years (435).

When renal carcinomas are detected presymptomatically treatment depends on size. Most small renal tumors enlarge slowly (<2 cm per year) (429), and once the growth rate of a given lesion is determined, it can be kept under radiographic surveillance. The cutoff for treatment is 3 cm diameter, and then nephron-sparing surgery or an alternative technique such as radiofrequency ablation is used (444,445). Repeated surgeries may eventually necessitate renal replacement therapy. Renal transplantation has been undertaken successfully (446).

**121.2.5.5 Pheochromocytoma.** Pheochromocytomas only occur in specific VHL subtypes (type two). Mean age

at diagnosis of pheochromocytoma in VHL is 30 years (435). The lesions are usually in the adrenal. Although extra-adrenal lesions can occur in VHL, the finding of an extra-adrenal lesion in a pheochromocytoma-only family makes a succinate dehydrogenase subunit mutation more likely. The symptomatology, diagnosis, and treatment of pheochromocytomas in VHL is the same as when these lesions occur in isolation (429).

**121.2.5.6 Pancreatic Lesions.** The most common pancreatic lesions in VHL are cysts; these are usually asymptomatic and found on screening (447). In one series, 21 of 52 patients (40%) who underwent screening with abdominal CT had pancreatic cysts (448). The earliest age they have been identified was 15 years; in screening programs they usually are picked up between 20 and 40 years. The other benign pancreatic lesion in VHL is the serous adenoma or microcystic adenoma, which was present in 4% of the Hough and colleagues series (448). Both cysts and microcystic adenomas are usually asymptomatic, but if they are large, or occur in a critical place (e.g. near the bile duct), they can be symptomatic. Occasionally the cysts are so numerous that pancreatic function is affected.

Solid pancreatic tumors in VHL are usually nonsecretory islet cell tumors (447,449–451). These can be malignant and surgery is recommended in tumors >3 cm in diameter.

**121.2.5.7 Other Lesions.** Papillary cystadenomas of the epididymis occur in up to 60% of men with VHL disease and are often bilateral (452). Unilateral papillary cystadenomas of the epididymis occur rarely in the general population. When they are bilateral, they are virtually pathognomonic of VHL disease. Epididymal cysts with no solid component are also commonly found in VHL patients; however, they are seen in 23% of the general population, making them an unreliable marker for VHL disease. These lesions rarely cause symptoms, and the cystadenomas are benign; surgery is therefore indicated only for the occasional patient who presents with symptoms. Women can develop papillary cystadenomas in the broad ligament, the embryonic counterpart of the epididymis. These lesions are exceedingly rare (429).

Endolymphatic sac tumors can be detected by MRI or CT imaging in up to 11% of VHL patients (453). Bilateral lesions are considered pathognomonic for VHL. The endolymphatic sac is located at the end of the lymphatic duct and lies within the dura of the posterior fossa. Sac tumors can grow outward into the cerebellum or cerebellopontine angle and thus mimic other tumors more commonly found at these sites. They can also erode the vestibular aqueduct to involve the inner ear structures. Symptoms reflect the direction of growth. These tumors are histologically similar to the papillary cystadenomas of the epididymis. They are locally invasive but not known to metastasize. The tumors can be treated by surgical resection (454).

**121.2.5.8 Natural History.** The introduction of screening programs for disease complications for VHL from the late 1980s onward has much improved the natural history. The study of Maher et al. (430) consisted largely of unscreened patients. The mean age at presentation of the symptomatic cases in the series was  $27 \pm 12.6$  years. As in the other phakomatoses, the natural history depends on which lesions develop; in unscreened populations the disease is associated with significant morbidity and mortality. In the Maher et al. series (430), 51 of 152 patients had died. Mean age at death was 41 years (range 13 to 67 years). Renal carcinoma was the most common cause of death (24 of 152 or 16%), followed by cerebellar hemangioblastoma (21 of 152, or 14%). Screening programs are improving the natural history of the disease. Wilding et al. (455) recently showed a significant increase in life expectancy before and after the introduction of a genetic register and routine surveillance of VHL families. The median life expectancy before introduction was 43.1 years (95% CI 39.2–47); this improved to 59.4 (95% CI 48.1–70.8). There remains, however, a cohort of patients for whom we have no satisfactory treatment. For example, patients with symptomatic optic disk angiomas usually lose vision, and those with multiple CNS hemangioblastomas may reach the stage at which further surgery is considered impractical and are left with severe neurologic deficits.

**121.2.5.9 Diagnostic Criteria and Differential Diagnosis.** Using the clinical diagnostic criteria for VHL (456), the diagnosis is made in the following:

- A simplex case (i.e. no known family history) presenting with two or more characteristic lesions (e.g. two hemangioblastomas or a hemangioblastoma and a visceral lesion).
- An individual with a positive family history and one or more of the following: retinal angioma, CNS hemangioblastoma, pheochromocytoma, multiple pancreatic cysts, epididymal or broad ligament cystadenoma, multiple renal cysts, or renal cell carcinoma before age 60 years.

The main problem in the diagnosis of VHL is that the condition is not considered in patients with isolated lesions that are part of the disease spectrum. Often the significance of other disease features in relatives is not appreciated, and the patient is discharged after treatment for the particular problem, only to present at a later stage with another disease feature.

Other causes of hereditary renal cancer such as hereditary leiomyomatosis and renal cell cancer and the Birt–Hogg–Dube syndrome have no other features that overlap with VHL (457).

**121.2.5.10 Genetics.** VHL disease is inherited as an autosomal dominant condition with almost complete penetrance by age 60 years. In their study, Maher's group (425) found that approximately 25% of cases were sporadic. The mutation rate was calculated to be in

the region of  $2.3\text{--}4.4 \times 10^{-6}$  per gamete per generation. There was no parental age effect for new mutations, and reproductive fitness was 0.89. As in the other phakomatoses, the disease in a proportion of the sporadic cases results from somatic mutation. Sgambati and colleagues (458) studied the apparently sporadic cases in the NIH VHL cohort. They showed two (4.8%) of the 42 to have parents mosaic for VHL. In VHL, when manifestations such as renal cancer do not present clinically until it is too late for satisfactory treatment, it is suggested that at least one round of screening be undertaken (and more depending on age) of apparently unaffected parents who are mutation negative on lymphocyte DNA.

**121.2.5.11 Heterogeneity and Genotype–Phenotype Correlation.** All families with VHL map to the same locus on chromosome 3 and in nonmosaic patients with classical VHL mutation detection is >95% (435). There is interfamily variation, with particular reference to pheochromocytomas and renal carcinoma. Families can be grouped into VHL subtypes as follows:

- Type 1: All the VHL features except pheochromocytoma occur. Truncating mutations or missense mutations that grossly disrupt the protein are associated with type 1 (459). A further subgroup of type 1 patients is sometimes referred to as 'type 1B'. These patients have deletion of all or part of the *VHL* gene and the *HSPC300* gene and have a very low risk of renal carcinoma (460–462).
- Type 2: This is VHL with pheochromocytoma and families usually have a missense mutation. Type 2 is further divided into three groups:
  - Type 1A: Low risk of renal carcinoma.
  - Type 2B: The most frequent type 2 subtype, with a high risk for renal carcinoma.
  - Type 2C: Pheochromocytoma is the only feature.

Maher et al. (435) feel that this classification is most useful in the research setting for correlating mutation with protein function; in the clinical setting, one has to be cautious not to use the classification too rigidly. They use the example of an index case with retinal angiomas and renal carcinoma who would be type 1, but the finding of a pheochromocytoma in a relative makes it a 2B kindred.

**121.2.5.12 Chuvash Polycythemia.** This is the only other phenotype associated with VHL mutations (463). It is autosomal recessive and is endemic in the Chuvashia region of Russia. In this region most people are homozygous for p.Arg200Trp mutation. Patients have elevated erythropoietin levels and thrombosis and/or hemorrhage can occur. No VHL disease features have been reported. Chuvash polycythemia is now recognized in many ethnic groups and with other mutations (464,465). VHL analysis is indicated in all patients with congenital erythrocytosis.

**121.2.5.13 Pathogenesis.** The *VHL* gene was localized to chromosome 3p by linkage (466–468), and tumors were found to display loss of heterozygosity for this region

(469,470), consistent with a tumor suppressor mechanism. The gene was cloned in 1993 by Latif and colleagues (467). The *VHL* gene has three exons and encodes for two VHL proteins, a full-length 213-amino-acid protein (pVHL<sub>30</sub>) and a smaller protein lacking the first 53 amino acids (pVHL<sub>19</sub>). Functional studies suggest that the two proteins have the same function (471). The VHL protein is widely expressed in fetal and adult tissues (472,473).

Hypoxia-inducible factor (HIF) is hydroxylated in the presence of oxygen, which targets it for ubiquitination and subsequent degradation. HIF is not hydroxylated in low oxygen conditions, allowing it to function as a transcription factor to induce genes involved in angiogenesis. Loss of VHL function prevents the ubiquitination of HIF and leads to localized hyperactivity of HIF, with resultant tumor formation. This mechanism suggests the possibility of use of inhibitors of angiogenesis in the treatment of VHL-associated tumors. VEGF levels rise in response to HIF activity. Understanding the disease pathogenesis has led to new therapeutic opportunities (435). Tyrosine kinase inhibitors that target the VEGF pathway have been shown to be effective in sporadic renal cancer (474). VHL-specific trials have shown good preliminary results in some tumors (475).

**121.2.5.14 Management.** The features of VHL disease that can cause significant morbidity and mortality are all potentially treatable if diagnosed early (429) (Figure 121-6). This has led to the development of screening protocols for the follow-up of affected individuals and their at-risk relatives. All individuals with VHL should be offered annual clinical review. Further clinical examinations and other screening techniques are added in at various ages for different disease manifestations. Additional examinations and investigations are instigated at different ages depending on the average age of presentation of the VHL manifestation being targeted. The following surveillance protocol is recommended (435).

*Screen for retinal angiomas:* Annual ophthalmic examinations (including both direct and indirect ophthalmoscopy) beginning in infancy or early childhood.

*Screen for CNS hemangioblastomas:* MRI scans of the head (and/or the spine) every 12–36 months beginning in adolescence.

*Screen for renal cell carcinoma and pancreatic tumors:* MRI or ultrasound examination of the abdomen annually from age 16 years. Although CT is the most sensitive method for detecting renal tumors, particularly in the presence of renal cysts, other methods are preferred for screening to avoid a large cumulative radiation dose.

*Screen for pheochromocytomas:* Annual blood pressure monitoring and biochemical screening for pheochromocytoma from early childhood. Measurement of plasma catecholamine metabolites is the most sensitive test and is replacing the traditional 24-hour urine collection in some centers. In families at high risk of pheochromocytoma the annual abdominal MRI should be introduced in childhood before 16 years.

Other investigations are driven by symptoms, for example, MRI of internal auditory canals if hearing loss, tinnitus, or vertigo is present. Although the screening protocols have been shown to decrease disease-related morbidity and mortality, patients with VHL may still have to face multiple treatment episodes to different body systems during their lifetime. This is compounded by the fact that the natural history cannot be predicted and that different family members can be affected in different ways. It is important when entering families into screening programs for the first time that the full implications of the screening program be discussed. This is particularly the case when the diagnosis is first made in adulthood and the first round of tests may identify multi-organ involvement, some of which will require treatment even though asymptomatic.

**121.2.5.15 Molecular Genetic Testing.** As the screening programs for VHL disease manifestation start in early childhood, VHL is one condition for which childhood genetic testing is justified. Even though molecular testing of children at risk of VHL in early childhood is justified clinically, the report of Levy and Richard (476) suggests that not all families will want to consider this. In our own practice, we give parents the option as to whether they want to consider having the children tested, or have the children enter the screening program until the time when the children can decide about gene testing on their own account. Mutations can be now identified in most patients, and this testing is routinely available in service laboratories. This enables only those shown to have inherited the mutation to proceed to the screening programs.

It is also recommended that patients presenting at a young age with any of the individual features of VHL be assessed for the disease (434,438,477). If screening for disease manifestations and mutation analysis is normal, it is unlikely that they have VHL; however, because of the possibility of mosaicism, as mutation detection is not 100% sensitive, and if they have VHL they would be at risk of life-threatening conditions such as renal carcinoma at an older age, long-term surveillance is recommended. In our own practice, if such patients reach the age of 50 with no manifestations, they are discharged from follow-up.

## 121.2.6 Other Phakomatoses

Several additional disorders display features of “spottiness,” with prominent effects on the nervous system that overlap with van der Hoeve’s original classification sufficient to be included among the “phakomatoses.” These include both inherited and sporadic disorders. The latter group was suspected on clinical grounds to be caused by genetic mosaicism (478) and this is now being confirmed at the molecular level with a series of mosaic overgrowth phenotypes resulting from mutations in the genes in the PI3Kinase-AKT

pathway. The clinical relevance of including them in this chapter is that their phenotypes can overlap with the classical phakomatoses, particularly NF1.

**121.2.6.1 PTEN Hamartoma Tumor Syndromes (PHTS).** *PTEN* hamartoma tumor syndromes (PHTS) is the collective name given to a group of overlapping disorders that predispose to hamartomas and certain malignancies and are caused by germline mutations in the *PTEN* gene on 10q23.3 (Phosphatase and TENsin homolog deleted on chromosome TEN (479–481)). One of the most consistent features of all the related phenotypes is macrocephaly. Inheritance is autosomal dominant.

**121.2.6.1.1 Cowden Syndrome (CS).** CS predisposes to a mixture of hamartomas and benign and malignant tumors of various organs. The most prevalent feature are the mucocutaneous manifestations, which are present in 99% of individuals by the third decade of life (481). The mucocutaneous manifestations include trichilemmomas (benign neoplasms derived from the outer root sheath of the hair follicle), papillomatous papules (benign epithelial neoplasms—on the skin and oral mucosa) and keratoses of peripheral parts of the body (acral), particularly the soles of the feet. In clinical practice, however, the significance of the skin features may not be appreciated until the patient presents with one of the benign or malignant tumor related to the disease or a relative is diagnosed with PHTS.

The tumor predisposition in CS gives an increased risk of benign and malignant disease in affected organs. For example, affected women have a risk of up to 67% of benign breast disease and an 85% lifetime risk of breast cancer with 50% penetrance by 50 years (481,482). The thyroid, uterus and bowel also show the mixed picture of benign and malignant lesions. Other cancers that occur at increased risk are renal papillary carcinoma and melanoma. When a rare CNS tumor, cerebellar dysplastic gangliocytoma (Lhermitte–Duclos disease), occurs in an adult it is pathognomic of CS.

**121.2.6.1.2 Bannayan–Riley–Ruvalcaba Syndrome (BRRS).** In contrast to CS, the BRRS phenotype is usually diagnosed in childhood in children presenting with macrocephaly often associated with frontal bossing and downslanting palpebral fissures. Birth weight is usually greater than 4000 g and length greater than the 97th centile (483). Postnatal growth decelerates and, other than the head circumference, the proportions of older patients are normal. Hypotonia, severe motor delay and subsequent moderate to severe learning problems are seen in up to 50% of cases, with seizures in up to 25% (483). Approximately 60% of cases have a proximal myopathy with a lipid storage picture on biopsy (484,485).

About 75% have lipomas, some of which can be aggressive and cause complications (486). Characteristic macular pigmentation is found on the penile glans and shaft in the majority of affected males; this may be subtle and needs to be sought for specifically. A few patients are reported as having café-au-lait spots.

Hamartomatous polyps cause symptoms more frequently than in CS, presenting with bleeding and intussusception (481). BRRS was not originally thought to be associated with an increased risk of malignancy, but as no clear genotype–phenotype correlation has emerged and in some families the BRRS and CS phenotypes coexist it is now recommended that patients with BRRS are followed up as patients with CS.

**121.2.6.1.3 PTEN-Related Mosaic Overgrowth/Type 2 Segmental CS.** A number of patients have been reported with germline *PTEN* mutations and a clinical picture dominated by a mosaic overgrowth pattern similar to that seen in Proteus syndrome (487–490). Some cases have been in classical CS families. Affected individuals have had a mixture of arteriovenous and lymphatic vascular malformations, lipomatous overgrowth and linear epidermal naevus. In cases where different tissues have been analyzed either a second somatic mutation or evidence of loss of heterozygosity has been found.

The nomenclature of these cases needs clarification. Eng (481) refers to Proteus syndrome and Proteus-like syndrome as part of Pitt–Hopkins syndrome (PTHS). However, no patient with classical PS has been found to have *PTEN* mutations and as discussed below has now been shown to result from somatic mutation in *AKT1* (491). Eng refers to this as “*AKT1*-related Proteus syndrome” and comments that as *PTEN* downregulates *AKT1* it can be viewed as a “*PTEN*-pathway-opathy.” Caux et al. (490) described two cases in CS families and suggested the acronym SOLAMEN for segmental overgrowth, lipomatosis, arteriovenous malformation and epidermal nevus. Although this describes the phenotype, it seems a retrograde step in the molecular era. Happle (492) proposed we use the term type 2 segmental Cowden disease, which fits with the classification he proposed for segmental manifestations of dominant skin disorders in 1997 (478).

**121.2.6.1.4 Other PTHS Phenotypes and Genes.** *PTEN* mutations have been found in 10–20% of patients ascertained through autistic spectrum disorders and macrocephaly (493,494).

Not all patients with CS clinically have *PTEN* mutations. Approximately 30% of such patients have a germline *KLLN* epimutation, which is associated with a greater frequency of breast and renal carcinoma (495). Germline variants in three of the succinate dehydrogenase genes (B, C and D) have also been reported in both *PTEN*-positive and *PTEN*-negative CS patients (496); in the former they appear to modify the risk of breast and thyroid cancer.

**121.2.6.1.5 Management of PTHS.** It is now recommended that all patients with *PTEN* mutations are followed using the surveillance recommendations originally developed for surveillance of patients with the CS phenotype (481). One child with a germline *PTEN* mutation and life-threatening respiratory dysfunction and malnutrition because of progressive hamartomas of

the chest, abdomen and pelvis showed dramatic response to the mTOR inhibitor, rapamycin (497).

**121.2.6.2 Proteus and Other Syndromes Caused by Constitutional or Somatic Mutation of Genes in the Phosphatidylinositol 3-Kinase (PI3K)-AKT Signaling Pathway.** This group of patients present with a combination of specific skin changes, dysregulated growth of one or more body parts or of a specific tissue type and vascular malformations. The majority of cases are sporadic and few, if any, convincing familial cases exist. In many cases the phenotype is very patchy or localized. These findings suggested new dominant mutations or somatic mutation of genes that would be lethal if germline. As systematic clinical research was applied it became clear that there were specific subgroups of patients. The importance of recognizing these subgroups was not just of academic interest; the natural history of the dysregulated growth and of specific types of vascular manifestation is different. Thus Biesecker and colleagues (498,499) developed very specific criteria for Proteus syndrome as it is the progressive overgrowth of parts of the body compared with the general growth rate that causes some of the major challenges for patients.

Oduber and colleagues (500) proposed a classification of entities combining vascular malformations and deregulated growth. However, this may well now be superseded by a molecular classification. The past year has seen a series of papers reporting germline and somatic mutations in genes in the PI3K-AKT pathway that have been identified as groups have applied improved sequencing technologies to search for mutations in different tissues from this group of patients (491,501–508). At an early stage it is clear that some phenotypes, such as Proteus, are due to a specific somatic mutation in one gene. Furthermore, in the three *AKT* genes the mutations are homologous (p.Glu17Lys) and the phenotypes reflect the tissues where the protein is most active during development.

### **121.2.6.3 Klippel–Trenauney–Weber Syndrome.**

**121.2.6.3.1 Clinical Features.** The main feature of Klippel–Trenauney–Weber syndrome (KTS) consists of a cutaneous vascular nevus over the trunk or limbs in an asymmetrical distribution (509). The nevus can be associated with varicosities, lymphatic anomalies, and asymmetrical hypertrophy of all or part of a limb—the nevus and hypertrophy need not necessarily overlap. The lesions are usually unilateral, but can also be bilateral. The hypertrophy of the limbs is due to hyperplasia of both bone and soft tissue, and arteriovenous anastomoses are found in occasional cases. The CNS is rarely involved (506,507). Pain control is an important component of clinical management (510,511).

**121.2.6.3.2 Genetics.** Most cases have been sporadic (512). Discordant monozygotic twins were reported by Hofer and coworkers (513). The vascular anomalies overlap with those seen in CLOVES. Kurek et al. reported *PIK3CA* missense mutations in lesional tissue from 3 of 15 individuals with KTS (501).

### **121.2.6.4 Encephalocraniocutaneous Lipomatosis.**

**121.2.6.4.1 Clinical Features.** Encephalocraniocutaneous lipomatosis (ECCL) is localized to the craniofacial area and some authors suggest it is a localized form of Proteus syndrome (514). Against this is the fact that the features are present at birth and are nonprogressive, with the exception of skeletal cyst and jaw tumors if present. The following are the main features:

- Cutaneous: Nonscarring alopecia,  $\pm$  underlying fatty tissue are the most frequent. The nevus psiloliparus is characteristic and is composed of a smooth, hairless fatty tissue nevus of the scalp.
- Ophthalmic: Choristomas,  $\pm$  other eye anomalies are present in most cases. They are benign ocular tumors and include epibulbar or limbal dermoids and lipodermoids.
- CNS anomalies: These include intracranial and spinal lipomas often in association with other abnormalities including porencephalic and arachnoid cysts. Intracranial calcification similar to that seen in SWS has also been described (504,505).
- Neurology: Patients exhibit a variable degree of developmental delay and epilepsy.
- Evidence of extracranial manifestations should be looked for (506–508).

**121.2.6.4.2 Genetics.** All cases of ECCL to date have been sporadic (515). ECCL has been reported in one patient in whom a germline *NF1* mutation has been demonstrated—the authors speculated that the ECCL may result from somatic mutation in the normal *NF1* allele or in another unrelated gene (516).

### **121.2.6.5 Sturge–Weber Syndrome/Encephalofacial Angiomatosis.**

**121.2.6.5.1 Clinical Features.** SWS is a congenital condition marked by capillary malformations of the facial skin in the distribution of the first division of the trigeminal nerve (port-wine stain/nevus). The other second and third areas of trigeminal supply may also be affected. The other features are cerebral venous malformations (leptomeningeal angiomatosis) and glaucoma with ocular venous vascular malformations. Only 8–20% of patients presenting with facial port-wine nevus develop neurological symptoms, and the diagnosis of SWS is only made with the combined brain involvement (517,518).

The cutaneous features are present at birth and are nonprogressive. The neurologic features of SWS seem to be a consequence of the leptomeningeal angiomata (519), although other cerebral vascular malformations may occur. The characteristic “tramline calcification” appearance results from gyriform calcification of the cerebral cortex and usually develops after 2 years of age. Seizures, mental retardation, and hemiparesis may occur. Developmental delay occurs in approximately 50% of affected individuals, although it is much less likely if there are no seizures and more likely if seizures began

in the first year of life (517,520). The seizures may be generalized or focal, affecting the contralateral side of the body. They may be difficult to control, and surgery should be considered if they remain refractory to medical treatment (521). The neurologic manifestations are often progressive.

SWS should be considered in any child with a facial capillary hemangioma, and radiologic studies are helpful in delineating the degree of meningeal and cerebral involvement. However, it should be noted that both CT and MRI studies can be normal in the newborn. Lo et al. (517) review developments in imaging techniques, and that of possible biomarkers, which will assist both in diagnosis and prognosis.

**121.2.6.5.2 Genetics.** All cases of SWS have been sporadic except for one reported case of an affected father and son (522). Monozygotic twins have been reported that were concordant (523,524) or discordant for the condition (525). The most likely explanation remains somatic mosaicism.

## ACKNOWLEDGMENTS

This chapter is dedicated to the memory of Dr Dick Lindenbaum, whose slide collection provided the clinical photographs of tuberous sclerosis. We thank Dr Simon Hobson and Dr Philip Anslow for providing the von Hippel–Lindau illustrations and Mr Bill Church for providing the illustration of Lisch nodules.

## Biographies

**Susan M Huson, MD, FRCP.** Dr Sue Huson is a Consultant Clinical Geneticist in the department of Genetic Medicine at the Central Manchester University Hospitals NHS Foundation Trust and an honorary senior Lecturer in Clinical Genetics at the University of Manchester. She trained in medicine in Edinburgh. After general training in adult medicine and neurology, she was a research fellow in Cardiff with Professors Peter Harper and Alastair Compston. She did a population based study of NF1 and gene mapping studies of NF1. Her work made a major contribution to the mapping of the *NF1* gene to chromosome 17 in 1987. Her MD degree, based on this work, was awarded with distinction and gold medal. She then trained in Clinical Genetics in London with the late Professor Robin Winter. As a consultant, first in Oxford and now in Manchester she has focused her clinical research on defining the different neurofibromatosis phenotypes and developing models of neurofibromatosis care. She is the director of one of the two English centers nationally commissioned for complex NF1 care.

**Bruce R Korf, MD, PhD.** Dr Korf received his MD degree from Cornell University Medical College and his Ph.D. degree in genetics and cell biology from Rockefeller University. He then completed training in pediatrics, pediatric neurology, and genetics at Children's Hospital, Boston. He served as clinical director in the Division of Genetics at Children's Hospital from 1986 to 1999 and as the medical director of the Harvard-Partners Center for Genetics and Genomics from 1999 to 2002. Currently he is the Wayne H and Sara Crews Finley Chair in Medical Genetics, Professor and Chair, Department of Genetics and Director, Heflin Center for Genomic Sciences at University of Alabama at Birmingham. Dr Korf has completed terms as president of the Association of Professors of Human and Medical Genetics, President of the American College of Medical Genetics, member of the boards of directors of the American College of Medical Genetics and the American Society of Human Genetics, member of the Liaison Committee on Medical Education, and the National Cancer Institute Board of Scientific Counselors. He currently is President of the ACMG Foundation for Genetic and Genomic Medicine and serves on the Board of Scientific Counselors of the National Human Genome Research Institute.

## Multiple Sclerosis and Other Demyelinating Disorders

*A Dessa Sadovnick*

Professor of Medical Genetics and Neurology, Director, endMS Western Pacific Research and Training Centre, University of British Columbia, Vancouver, BC, Canada

This article is a revision of the previous edition article by Dessa Sadovnick and George C Ebers, volume 3, pp 2851–2855, © 2007, Elsevier Ltd.

### 122.1 INTRODUCTION

Demyelination occurs when normal functioning myelin sheaths—lipid-rich insulators that surround axons in the central nervous system (CNS) and the peripheral nervous system—are broken down. The most common inherited demyelinating disease is multiple sclerosis (MS), which affects approximately 0.1% of Caucasians of northern and central European ancestry. This chapter will focus on MS (<http://mssociety.ca>, <http://www.nationalmssociety.org>, <http://www.mscares.org>), although brief reference will be made to a few other inherited demyelinating diseases.

MS is an inflammatory disease of the CNS characterized by myelin loss, varying degrees of axonal pathology, and progressive neurological dysfunction. MS is the most common cause of nontraumatic neurological disability in young adults in Europe and North America. The clinical onset of MS may be monosymptomatic or polysymptomatic. Onset symptoms can include sensory disturbances (numbness, tingling), visual disturbances (optic neuritis, diplopia), motor weakness and ataxia. The diagnostic criteria for MS have evolved over time (1,2), most recently to include findings on magnetic resonance imaging in the definition of dissemination in time and space (3). The most frequent revisions to diagnostic criteria also take into account the observation that MS is now recognized increasingly in pediatric (4) and non-Caucasian populations (3) (see Figure 122-1 for geographic distribution of MS).

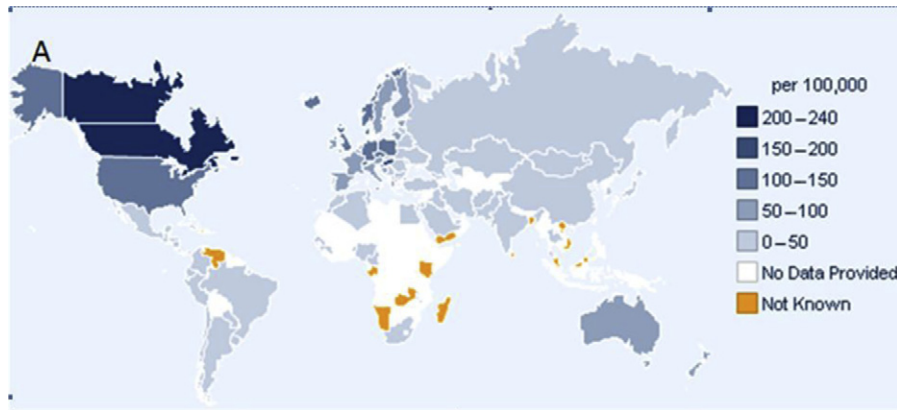

Prognosis cannot be accurately determined, but MS tends to be a progressive disorder with the majority of relapsing-remitting cases becoming progressive over time, as shown by several natural history cohorts (5–8). While not a fatal disease, a reduced life expectancy (about 10 years) has been reported (9).

MS disability is often assessed using the Extended Kurtzke Disability Scale or EDSS (10). The EDSS scale ranges from “0” to “10.” Zero refers to no disability, 6 is “needs a cane,” 8 is “bedridden” and 10 is “dead from MS.” Although this scale has definite limitations, it remains the most widely accepted disability and clinical measurement when evaluating the natural progression and outcome of clinical trials (e.g. beta-interferon-1b (INFB) 16-year follow-up) in MS (11).

Genes have important roles in MS susceptibility, with the human leukocyte antigen (HLA) class II locus exerting the strongest effect on MS risk (12). However, it is also very clear that broad, population-based environmental (nongenetic) factors are also very influential in determining disease susceptibility/protection (e.g. (13,14)). Thus, it is now accepted that genes, environment, and interactions between genes and the environment are important in the etiology of MS (e.g. (12–14)).

Current data provide evidence for the following statements (15–19):

- There is a true familial aggregation of MS;
- The familial aggregation is because of genetic material shared by individuals and not the shared familial microenvironment;
- Factors determining geographic distribution of MS are not operative in familial microenvironment but at a broad population level and exert a huge effect;
- The rate of MS is increasing but too rapidly to be due to genetic factors; environmental changes must be critical;
- There are probably different genetic and environmental triggers or agents involved in MS onset versus MS progression;
- MS natural history does not run true in families;
- Parental and gender effects are important in MS risk and allele transmission;

**FIGURE 122-1** Global MS prevalence. Maps courtesy of the Atlas of MS database (<http://www.atlasofms.org/index.aspx>).

- MS is not a “transmissible” disease in either childhood or adulthood, other than by genes;
- There is no evidence for a single deterministic gene/locus/allele in MS (not even HLA);
- The genetic interactions in MS are much more complex than initially believed;
- The “critical window of opportunity” to prevent MS may be much earlier than puberty;
- There are no biomarkers to definitively predict the clinical onset of MS;
- A maternal effect is well validated;
- Genetic factors have a role(s) in MS course as well as susceptibility;
- Epigenetic factors are increasingly being recognized;
- Evidence from studies of disease risk in relation to the month of birth implicates early-life environmental factors in MS susceptibility;
- Migration data together with variability in disease onset and relapse rates suggest that environmental factors might also act later in life influencing MS risk and disease course;
- Vitamin D is an attractive candidate risk/protective factor implicated by the association of MS risk with latitude and month of birth, and is likely to act early in life;
- Epstein–Barr virus (EBV) seems to act in adolescence or early adulthood to alter MS susceptibility;
- Smoking is associated with increased susceptibility to adult-onset MS when individuals are exposed later in life, and can alter the course of established MS;
- Strategies aimed at preventing or treating MS by manipulating environmental factors may provide a powerful way of reducing the prevalence.

Genes have been implicated in MS since the first linkage reports in the 1970s, with HLA and familial cases of the disease being reported as early as 1933 (15). In the mid-1990s, the first generation of genomic screens for linkage in MS were performed using a variety of methodologies and family types. These implicated many distinct regions of interest,

although with little consensus. The one exception was the major histocompatibility complex (MHC) on chromosome 6p21, which was first noted to have linkage with MS in the 1970s (15,17–19). Genome-wide association studies (GWAS) in MS led to the identification of additional loci of interest (20–24) but HLA class II extended *HLA-DRB1\*15* haplotype (*HLA-DRB5\*0101*–*HLA-DRB1\*1501*–*HLA-DQA1\*0102*–*HLA-DQB1\*0602*) has remained the most consistent association (25).

Replication and meta-analyses following GWAS have suggested up to 20 genes affecting MS susceptibility including *CD6*, *CD25* (interleukin 2 receptor, alpha, *IL2RA*), *CD40*, *CD58*, *CD226*, C-type lectin domain family 16, member A (*CLEC16a*), ectopic viral integration site 5 (*EVI5*), glypican 5 (*GPC5*), regulator of G protein signaling 1 (*RGS1*), tyrosine kinase 2 (*TYK2*), tumor necrosis factor receptor superfamily member 1A (*TNFRSF1A*), interferon regulatory factor 8 (*IRF8*), ribosomal protein L5 (*RPL5*), kinesin family member 21B (*KIF21B*), membrane metalloendopeptidase-like 1 (*MMEL1*), methyltransferase like 1 (*METTL1*), but additional, independent replication is still necessary for several genes and none meet the level of the *HLA-DRB1* (17–19,26). Even with respect to HLA, the genetics of MS remain complex and topics continuing to be studied include epistatic effects and parent origin effects to name a few (see (27–30)). This is clearly shown in Figure 122-2 (31) as it is the HLA haplotype and not the specific allele that influences risk/susceptibility to MS (e.g. 15/15 versus 15/04 (Figure 122-2)).

Thus, despite progress, the genetics in MS remains a conundrum and work must continue along several avenues (see (17,19)).

A number of strategies have been employed to dissect the environmental from the genetic components (i.e. nature versus nurture) underlying MS susceptibility, e.g. half-sibling, adoptee, step-sib and conjugal MS studies; see review articles (17,32) for descriptions

**FIGURE 122-2** Genotype relative risk for DRB1.

of these studies. Taken together, these have clearly shown no evidence for environmental factors operative within the familial microenvironment, either in childhood or adulthood. Thus, DNA sharing is responsible for most, if not all, of the familial aggregation of MS.

Half-sibling data initially suggested a maternal effect for MS (recurrence risk for maternal half-sibs was 2.35% compared to 1.31% for paternal half-sibs (33)), despite the mothers not having MS. This maternal effect has since been replicated in a Dutch extended pedigree (34), a study of avuncular pairs (35) and an investigation of interracial matings (36). The mechanism of the increased risk conferred maternally remains to be elucidated but epigenetic (study of changes in gene expression that may or may not be heritable and do not stem from a change in the DNA sequence (37)) mechanisms are implicated (38). Epigenetic marks (mainly DNA methylation and histone modification) can be modulated by the environment, thus integrating the external environment and internal genetic systems (28,39,40). At present, there are three major environmental factors associated with the risk of developing MS (32,41): (i) latitude and sunshine exposure and the resulting vitamin D levels, which are closely related, (ii) EBV seropositivity, and (iii) smoking. For a review of MS observations with potential regulation through epigenetics, see (42). Research into epigenetic mechanisms of MS continues.

## 122.2 PEDIATRIC MS

MS is increasing being diagnosed in children (43), often within 3 years of an acquired demyelinating syndrome (ADS) (see (4)). Recent diagnostic criteria for MS have recognized pediatric MS (4). For an overview of pediatric MS, see Reference (44). It still remains unclear whether susceptibility risk factors for pediatric MS are the same as those in adult-onset MS. Work continues in this area. HLA-DRB15 is a risk factor in both groups (45), and the role of EBV remains unclear (e.g. risk factor, protective factor, etc. (4,46)), as does race/ethnicity (47). Recurrence risks are yet to be validated in pediatric MS but at present appear to be lower than for adult-onset MS. However, rates may be confounded by an increased number of “at risk” relatives in families of pediatric cases (see Reference (48)).

## 122.3 PRACTICAL APPLICATIONS OF GENETIC STUDIES

### 122.3.1 Presymptomatic Treatment of MS

Given the anticipated complexity associated with the genetics of MS, it is unlikely that predictive testing (genetic or biomarkers) will be an option in the very near future; however, work continues to identify biomarkers of MS in asymptomatic individuals. There are several international groups working on the identification of

reliable and replicable MS biomarkers. Even if a presymptomatic biomarker is identified, one cannot ignore issues including who would define the cutoff for “at risk” individual (e.g. physician, drug company, etc.) and at what age would any preventive therapy be initiated. There is increasing evidence that vitamin D may have a preventive role in childhood, adulthood and even as early as conception and gestation. There may also be interactive effects between vitamin D, EBV and genes (e.g. (14,49–53)). There is also increasing interest in prodromal pathways in MS, which, if identified and replicated, may indicate windows of opportunity to potentially reverse early disease processes before clinical MS becomes evident. This is important for both adult-onset (54) and pediatric MS (4).

### 122.3.2 Genetic Counseling

Genetic counseling for MS must take into consideration the known facts, the complexity of the disease susceptibility and the as yet unknown factors and stochastic events. As shown in Figure 122-3, up to 30% of MS patients have at least one biological relative with MS based on data from the longitudinal, population-based Canadian Collaborative Project on Genetic Susceptibility to MS (CCPGSMS) (e.g. (33,35,55)).

Genetic epidemiological data suggest that genetic counseling must take into account individual family structure, i.e. family-specific factors such as gender, age of MS onset for affected relatives, twin status and whether any (both) parent has MS.

A “liability” threshold model may be helpful when explaining to consultants that each individual, controlling for ethnicity, has a certain amount of “genetic” and “nongenetic” risk factors, which together represent the person’s “liability” (or overall risk). Once the total liability is sufficient to cross a threshold, MS is clinically manifested. This explanation makes no assumption about the exact nature of the individual liability (genetic/environmental and interactions thereof). Nevertheless, taking covariates of age of onset, gender and parental MS status into account, it is likely that genetic loading may vary especially in view of the “nongenetic” factors that affect the population in general (e.g. climate, hours of sunlight) rather than the family-specific environment, as has been discussed previously in this chapter.

Lifetime risks for biological relatives of persons with MS, controlling for the amount of genetic sharing, are given in Table 122-1.

Depending on the amount of genetic (DNA) sharing, the recurrence risks for MS can range from 2/1000, i.e. the general population lifetime risk for Caucasians (e.g. adopted sibs, step-sibs), to 340/1000 (female monozygotic co-twins of MS probands with whom they share 100% of their genetic material).

**Demographics of CCS participants:  
Distribution of Familial MS**

**FIGURE 122-3** Demographics of CCS participants distribution of familial MS.

When counseling full sibs of affected individuals, risks can be refined from those given in Figure 122-1 when information is available on gender of the MS proband and the sib (56).

During genetic counseling sessions, patients and family members often ask the following questions, which can now be answered as follows:

- (1) Can my family members also “inherit” MS if I have MS?

MS itself cannot be directly inherited as is the case for a single gene disorder (such as cystic fibrosis and Huntington’s disease). However, a genetic susceptibility (“risk”) to develop MS does exist. This is highlighted by the fact that the increased frequency of MS among family members only holds true for family members who share genetic material (DNA). Family members who grow up together in the same environment but do not share genetic material (e.g. adopted brothers and sisters, as well as step-siblings) have no increased risk to develop MS compared to the general population.

Conversely, if you do share genetic material, your risk does not change whether you were “raised together” or “raised apart” from the family member who eventually develops MS. The risk of MS among family members can be influenced by several factors including gender, ethnicity, country/location where one grows up, age and biological relationship (percentage of DNA sharing) to other family members with MS.

If you are concerned about your risk to develop MS because you have other family members with MS or you are worried about the risk of passing on MS because you and another family member have MS, please contact genetic counseling services in your area for more information (<http://www.nsgc.org>; [cam medical org](#)).

**TABLE 122-1** Recurrence Risk of Multiple Sclerosis by Relationship

Relationship	Percent
First-degree relative; index case only MS	3.0
Monozygotic female co-twin	34.0
Dizygotic co-twin	5.4
Adopted sib	0.2
Maternal 1/2 sib	2.2
Paternal 1/2 sib	1.2
Step-sib	0.2
Offspring of conjugal mating	30.5
Offspring of consanguineous mating	9.0
Sister of female MS patient with onset under 30 plus 1 affected parent	12.7

**TABLE 122-2** Topics to be Included in Reproductive Counseling for Individuals with Multiple Sclerosis

<i>Effects of MS on Pregnancy</i>
Contraception <sup>a</sup>
Conception <sup>a</sup>
Pregnancy management
Pregnancy outcome <sup>a</sup>
<i>Effects of Pregnancy on MS</i>
Short-term
Long-term
<i>Recurrence Risks<sup>a</sup></i>
Factors to include in determining recurrence risks include gender, ages, family structure, simplex or multiplex with respect to MS, ethnicity, consanguinity, conjugal mating, etc. (See Table 122-1).
<i>Teratogenicity of MS Treatments<sup>a</sup></i>
Symptom specific
Relapses
Disease modifying
<i>Psychosocial Issues<sup>a</sup></i>

<sup>a</sup>Important to discuss regardless of whether it is mother or father who has MS.

Data from Dwosh, E.; Guimond, C. G.; Sadovnick, A. D. Reproduction Counseling in MS: A Guide for Healthcare Professionals. *Int. MS J.* 2003, 10, 67.

- (2) Can my child “catch MS” if he or she hugs, kisses or shares a cookie with my relative (e.g. mother, mother-in-law, sister) who has MS?

MS is not a transmissible disease and cannot be caught by human contact either during childhood or adulthood. This is clearly shown by a variety of genetic epidemiological studies, which have repeatedly shown this finding in separate groups (e.g. adoption, step-sib and conjugal studies discussed earlier in this article).

- (3) If my relative also develops MS, will he or she have the same clinical course of the disease that I do?

The clinical course of MS does not appear to “run true” in families if more than one family member is

affected. Thus, if you develop MS, you cannot assume that you will have the same disease course as your mother, sister, or other relative with MS.

- (4) Can you predict, in advance of any signs or symptoms, who is destined to develop MS in the future?

There are no definitive biomarkers for MS. A biomarker can be “anatomic, physiologic, biochemical, or molecular parameters associated with the presence and severity of specific disease states” (<http://www.biomarkers.org/NewFiles/faqs/definition.html#Anchor-What-35882>). This means that if you study two large groups, for example, 1000 MS patients and 1000 unaffected controls, you may find “risk factors” occurring more often in the affected group than in the controls, but these risk factors will still exist in both groups. Thus, you cannot test an unaffected person for a specific biomarker (such as HLA genotype or low levels of vitamin D) and then state with any certainty whether a person with or without this factor will end up being affected or unaffected by MS in the future. Hence we use the term “susceptibility” with respect to MS risk rather than “causal.”

- (5) Can MS be prevented?

There is no way to prevent MS. No fault can be assigned if someone develops MS. There are no clear protective preventive measures that can be taken.

- (6) If I have MS, should I have or father a child?

Much is still to be known about reproduction and MS. If you have MS and are planning to get pregnant or to father a child, you may want to discuss various issues involved in the decision-making process with your health care professionals. There is no right or wrong answer. Each couple must make their own informed decision. Topics to consider include the risk of pregnancy on MS, the risk of MS on pregnancy, possible risks of MS therapy at the time of conception and/or gestation, psychosocial issues, and the long-term commitment to raising a child (e.g. see References (57,58)). Please note that while several factors should be considered in advance, many individuals with MS have been able to successfully raise children.

- (7) If I am from a region where MS is rare (e.g. Shanghai, China) and am Chinese, do I change my risk to develop MS when I move to Canada or the northern United States? Do my genes change?

Although your genes do not change when you move, your environment does. Thus, by moving from Shanghai to Canada/United States, you may have a higher risk of developing MS than if you stayed in Shanghai. This may be due to different environmental exposures as well as genetic and environmental interactions (59,60).

### 122.3.3 MS Treatment—Risk of Teratogenicity

The majority of MS patients have the disease onset during their reproductive years and it is well known that females develop the disease up to three times as often as males. It is therefore imperative to weigh the pros and cons of current immunotherapies and other treatments (61) against potential teratogenic effects on developing fetuses when young females with MS are contemplating pregnancy or males are planning to father a pregnancy. Data are insufficient to answer with any degree of certainty whether such treatments would have effects on the developing fetus and/or the child's immune system over the long term.

**122.3.3.1 Other Demyelinating Diseases of the CNS.** Unlike MS, for which multiple genes, gene–gene, gene–environment and even environment–environment interactions are implicated, the following examples are relatively rare and are single gene disorders. In addition, as does MS, these examples have both adult and childhood subtypes.

### 122.4 KRABBE DISEASE (GLOBOID CELL LEUKODYSTROPHY)

Krabbe disease (globoid cell leukodystrophy) is an autosomal recessive disorder (25% sibling recurrence, 67% chance that asymptomatic siblings are carriers, females are affected as often as males) resulting from the deficiency of galactocerebrosidase (GALC), leading to the accumulation of a cytotoxic metabolite (galactosylsphingosine or psychosine), which results in the apoptosis of myelin-forming cells (62,63). The estimated carrier frequency is 1/150 for the general population. Prenatal diagnosis is possible either by measurement of GALC enzyme activity or by molecular genetic testing if both disease-causing alleles in an affected family member are known (62).

Recent guidelines have been developed as an educational resource for confirmatory testing and subsequent clinical management of presymptomatic individuals suspected to have a lysosomal storage disease, including Krabbe disease as well as a research agenda for longitudinal studies (64).

### 122.5 METACHROMATIC LEUKODYSTROPHY

Common forms of arylsulfatase A deficiency (metachromatic leukodystrophy or MLD) are infantile, juvenile and adult (66). Although all forms of MLD follow the autosomal recessive mode of inheritance, each form appears to be a distinct genetic entity and the type seems to run true in families. Pseudo-aryl sulfatase A deficiency has been reported.

Genetic counseling is based on the autosomal recessive model but there are reports of cases in which one

copy of the *ARSA* gene has been deleted and a single disease-causing *ARSA*-MLD mutation on the remaining allele results in MLD. Therefore, mutation testing is recommended for both parents when counseling recurrence risk data for other family members (65). There is evidence for a genotype–phenotype correlation (66).

Recent guidelines have been developed as an educational resource for confirmatory testing and subsequent clinical management of presymptomatic individuals suspected to have a lysosomal storage disease, including MLD, as well as a research agenda for longitudinal studies (64).

### 122.6 X-LINKED ADRENOLEUKODYSTROPHY

Adrenoleukodystrophy shows a wide range of phenotypes, with the two most common being the childhood and adult forms. Intragenic deletions of the adrenoleukodystrophy gene and point mutations have been identified, although most families have unique mutations. About 93% of cases have inherited the *ABCD1* mutation from one parent; at most, 7% of individuals with X-ALD have a de novo mutation. Males who inherit the mutation will be affected (67,68). Mosaicism has recently been identified (68). About 20% of females who are carriers develop neurologic manifestations but have later onset (age = 35 years) and milder disease than do affected males (67).

### Biography

**Dr Sadovnick** was born in Montreal and obtained degrees from McGill University (BSc, Honors Genetics; MSc, Human Genetics) and the University of British Columbia (PhD, Genetics). Dr Sadovnick is a Professor in the Department of Medical Genetics and the Faculty of Medicine, Division of Neurology, UBC. She is the director of the Western Pacific Regional Research and Training Center for Multiple Sclerosis (MS), established by the MS Society of Canada. Dr Sadovnick is the Principal Investigator of several multicenter Canadian and International collaborative research projects on multiple sclerosis, pediatric multiple sclerosis and dementia. Dr Sadovnick was one of the developers of the MSc Genetic Counseling Training Program at UBC and has served as codirector and is now on the advisory panel. She has published extensively (over 300 articles in peer-review journals) and serves as a reviewer for a wide variety of medical journals and grant review panels. She is often an invited speaker at Canadian, American and International (Europe, South America, Russia, Asia) scientific meetings and task forces. Dr Sadovnick is a member of several international advisory groups for both MS and dementia. She is currently involved in Canadian–Chinese initiatives in both MS and early onset familial Alzheimer’s disease (AD).

## Genetics of Stroke

Mateusz G Adamski and Alison E Baird

SUNY Downstate Medical Center, Department of Neurology, Brooklyn, NY, USA

This article is a revision of the previous edition article by Martin Dichgans and James F Meschia, volume 3, pp 2856–2879, © 2007, Elsevier Ltd.

### 123.1 INTRODUCTION

Strokes result from a focal reduction of blood flow to the brain. Around 83% of strokes are due to arterial vascular occlusion (termed *ischemic stroke*) and around 17% are due to vascular rupture (termed *hemorrhagic stroke*). Arterial vascular rupture may occur into the brain parenchyma resulting in intracerebral hemorrhage (ICH) or into the subarachnoid space what results in subarachnoid hemorrhage (SAH). In about 1% of cases, strokes occur in the venous system (termed cerebral venous thrombosis). Strokes are a leading cause of morbidity and mortality in the US. There is a substantial additional burden of asymptomatic cerebrovascular disease.

Evidence for a genetic basis for stroke comes from twin and family studies. Furthermore, a number of monogenic disorders cause stroke, as either a primary manifestation or a secondary manifestation. The contribution of these factors has been increasingly recognized over the past 10–20 years with the description of monogenic disorders such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). Advances in genomics methods, including genome-wide association studies, are permitting possible new genetic risk markers to be explored.

In this chapter, we will review the genetics of stroke and cerebrovascular disease. The burden and prevalence of stroke, along with stroke classification systems, will first be described. Then, evidence from twin and family studies will be presented followed by monogenic disorders associated with stroke.

#### 123.1.1 Prevalence and Incidence

Stroke represents a serious burden to the worldwide population in terms of prevalence, incidence, long-term disability, and mortality, generating substantial costs across the globe. Stroke statistics differ by gender, age groups, and among the four main racial groups: Whites, Asians, Blacks and Hispanics. According to an estimate,

7,000,000 Americans of  $\geq 20$  years of age have had a stroke, setting the stroke prevalence at the level of 3.0%. Another projection is that by 2030, another 4 million will suffer from stroke, increasing the prevalence by 24.9% (1). Every year, 795,000 people experience a new (77%) or recurrent stroke (23%). Gender and racial differences are seen in both stroke prevalence and incidence, with higher overall incidence in women and the highest incidence and prevalence in non-Hispanic blacks (1). The distribution of stroke subtypes has not changed since 2011, with 87% of ischemic strokes, 10% of hemorrhagic strokes, and 3% of SAH strokes (2). Over the past 20–30 years, stroke incidence has declined significantly in whites, both in men and women (3). Differences in stroke prevalence and incidence between blacks and whites highlight the importance of race.

#### 123.1.2 Mortality

Stroke is now the 4th leading cause of death behind the causes of the diseases of the heart, cancer, and chronic lower respiratory diseases. In the US, a person suffers a stroke every 4 minutes and stroke causes 1 of 18 deaths (1). The 30-day mortality is 12.6% for all strokes, 8.1% for ischemic strokes, and 44.6% for hemorrhagic strokes (4).

#### 123.1.3 Common Stroke Risk Factors

Common stroke risk factors include the following: high blood pressure, atrial fibrillation (AF), smoking, diabetes mellitus (DM), transient ischemic attack (TIA), dyslipidemia, renal disease and sleep apnea, and physical inactivity. TIA substantially increases the short- and long-term stroke rates (1). High blood pressure nearly doubles the lifetime risk of stroke (5). Impaired glucose tolerance and DM respectively doubles and triples the risk of stroke (6). AF independently increases the risk of stroke by five fold throughout all ages (7). Smoking is the most important modifiable stroke risk factor that increases 2 to 4 times the risk of stroke among current smokers (8).

### 123.1.4 Poststroke Long-term Disability

Stroke is a leading cause of serious, long-term disability in the US (1). Neurological deficits, hemiparesis and cognitive deficits at six months poststroke, are present in almost half of the patients. Hemianopia, aphasia, and sensory deficits are present respectively at 19.6, 18.9 and 15.4% of patients. In addition, women were found to be at greater risk for disability and institutionalization (9).

Stroke imposes a substantial economic burden both for society and individual. In the US, the mean stroke expense was \$ 7657 per person in 2007, and the mean estimated stroke care lifetime cost is estimated at \$ 140 048 (1).

## 123.2 STROKE PHENOTYPES

An understanding of stroke classification is essential in reviewing stroke genetics. This is because the different monogenic disorders are specifically associated with certain stroke types and subtypes. According to the World Health Organization, stroke was defined in the 1970s as “neurological deficit of cerebrovascular cause that persists beyond 24 hours or is interrupted by death within 24 hours” (10). Stroke is a heterogeneous disease represented by five main types: ischemic stroke, hemorrhagic stroke, subarachnoid stroke, cerebral venous thrombosis and spinal cord stroke. Furthermore, ischemic stroke is subdivided into four etiological categories: atherothrombotic, small-vessel disease, cardioembolic, and other causes Table 123-1.

### 123.2.1 Ischemic Stroke—Subtypes, Pathomechanism

Ischemic stroke occurs when a blood vessel that supplies the brain is occluded by a clot. There are two kinds of clots: thrombus and embolus. Thrombus forms in an artery that is already narrow and causes thrombotic stroke. Embolus is a clot that forms in another place

in the blood vessels of the brain, or some other part of the body, and travels up to the brain to block a smaller artery causing an embolic stroke.

Ischemic stroke may be divided into three categories, based on the clot source. It may arise from the atherosclerotic large cerebral arteries (e.g. carotid, middle cerebral, or basilar arteries) or atherosclerotic small cerebral arteries (e.g. lenticulostriate, basilar penetrating, and medullary arteries); finally, ischemic stroke may also be cardioembolic in origin.

**123.2.1.1 Large-Vessel Disease.** Large-vessel disease (LVD) or artery-to-artery embolism accounts for 15 to 20% of all ischemic strokes (12). In the case of LVD, emboli may originate from the aorta, extracranial carotid, or vertebral arteries, or intracranial arteries. The embolic material is composed of clot, platelet aggregates, or plaque debris that usually breaks off from atherosclerotic plaques (13).

**123.2.1.2 Cardioembolic Stroke.** Cardioembolism accounts for 20 to 30% of all ischemic strokes (12). Embolus originating from the heart causes severe strokes, but it is also prone to early recurrence. Due to their large size, cardiac emboli flow to the intracranial vessels in most cases and cause massive, superficial, single large striatocapsular or multiple infarcts in the middle cerebral artery.

**123.2.1.3 Small-Vessel Disease.** Small-vessel disease (SVD) accounts for another approximately 20 to 30% of all ischemic strokes (12). It is strongly associated with hypertension and is characterized pathologically by lipohyalinosis, microatheroma, fibrinoid necrosis, and Charcot–Bouchard aneurysms.

**123.2.1.4 Other Causes.** This category includes rare causes of stroke. Patients assigned to this group should have clinical and imaging signs of a stroke. Common causes of stroke (SVD, LVD, and Cardioembolism) should be excluded (14).

**123.2.1.5 Intermediate Phenotypes.** Patients are assigned to this group if the cause of stroke cannot be determined. This applies to patients with two or more potential causes of stroke, for example SVD and LVD or LVD and Cardioembolism.

**TABLE 123-1 Annual Ischemic Stroke Incidence Rates per 100, 000 among Whites, Blacks, and Hispanics (11)**

Ischemic Stroke Subtype	Whites %	Hispanics %	Blacks %
Large-vessel disease (LVD)	9.09	14.77	16.75
Intracranial LVD	3.41	8.72	7.85
Extracranial LVD	5.68	6.04	8.90
Small-vessel disease	14.77	20.81	20.94
Cardioembolic	23.86	20.13	17.28
Cryptogenic	51.14	44.30	42.93
Other	1.14	0.67	1.05
Total			

### 123.2.2 Hemorrhagic Stroke—Subtypes and Pathomechanisms

Hemorrhagic stroke results from a weakened vessel that ruptures and bleeds into the surrounding brain. The blood accumulates and compresses the surrounding brain tissue. There are two distinct mechanisms for two main types of hemorrhagic strokes: bleeding directly into the brain parenchyma (ICH), or bleeding into the cerebrospinal fluid containing sulci, fissures, and cisterns (SAH). Other disorders involving bleeding inside the skull include epidural and subdural hematomas, which are usually caused by a head injury and are not considered strokes.

**123.2.2.1 Intracerebral Hemorrhage.** Primary spontaneous ICH occurs as a result of the spontaneous rupture of small blood vessels damaged by hypertension or amyloid angiopathy. This has an incidence of 7–17 per 100,000 and accounts for 78–85% of all cases (15). Secondary spontaneous ICH occurs in the presence of a preexisting lesion such as avascular or parenchymal abnormality, the most common cause being arteriovenous malformations. Other causes include arteriovenous malformations, cavernous hemangiomas, intracranial aneurysms, venous sinus thrombosis, hemorrhagic transformation of ischemic stroke, coagulopathy, intracranial tumors, or vasculitis.

**123.2.2.2 Subarachnoid Hemorrhage.** Rupture of a cerebral aneurysm is the most common cause and accounts for about 85% of SAH. Cerebral aneurysms are present in about 2% of asymptomatic adults. Intracranial aneurysms are found in 2–5% of all autopsies; however, the incidence of rupture is only 2–20/100,000 individuals/year (16). Nonaneurysmal perimesencephalic SAH accounts for 21–68% of angiography negative SAH (17). The presentation of this subgroup is typically indistinguishable from other types of SAH, but their prognosis is excellent.

### 123.2.3 Cerebral Venous Thrombosis

Cerebral venous thrombosis (CVT)—i.e. thrombosis of the intracranial veins and sinuses—is a rare type of cerebrovascular disease that affects about five people per million and accounts for 0.5% of all strokes (18). The risk factors for venous thrombosis in general are linked classically to the Virchow triad of stasis of the blood, changes in the vessel wall, and changes in the composition of the blood. Risk factors are usually divided into acquired risks and genetic risks (19).

### 123.2.4 Spinal Cord Stroke

Spinal cord infarction is uncommon and accounts for 1.2% of all strokes (20). It is a rare but often devastating disorder caused by a wide array of pathologic states. The onset of spinal cord infarction is typically abrupt, and the vascular territory involved largely defines neurologic presentation.

### 123.2.5 Stroke Classification

It is not always possible to identify a specific cause of stroke; in fact, most registers failed to do so in 25–39% of stroke patients (21). Number of classifications on stroke subtype have been published. Their purpose was to uniformly classify patients for clinical trials, genetic, or epidemiological studies and to help classify patients for therapeutic decision making in daily practice.

Stroke Data Bank Subtype Classification (22) recognized five major groups: brain hemorrhages; brain

infarctions; cardioembolic stroke; lacunar stroke; and stroke from rare causes or undetermined etiology.

The Oxfordshire Community Stroke Project (OCSP) was proposed to characterize this population-based epidemiological study. This classification was based on clinical findings only. OCSP classification recognized four types of stroke: lacunar infarct (LACI); total anterior circulation infarct (TACI); partial anterior circulation infarct (PACI); and posterior circulation infarcts (POCI).

The Trial of ORG 10172 in Acute Stroke Treatment (TOAST) classification is the most commonly used by clinical researchers (14). This classification is used to categorize ischemic stroke etiology into five groups: large-artery atherosclerosis; cardioembolism; small-vessel occlusion (lacunae); stroke of other determined cause; and stroke of undetermined cause.

## 123.3 HERITABILITY: TWIN AND FAMILY STUDIES

In twin studies, the concordance rates for stroke are 17.7% in monozygotic twins and 3.6% in dizygotic twins (23,24). The heritability of stroke has varied in family studies, but allowing for some methodological weaknesses, it appears that a family history of stroke increases a subject's stroke risk by 2- to 3-fold (25,26). In the Framingham study, using the information obtained across three generations, including the original and offspring cohorts, a parental history of stroke was associated with an approximately 2-fold increase in stroke risk: a paternal history of stroke was associated with a relative risk of 2.4 and a maternal history with a risk of 1.4 (25). In later studies, looking at the heritability of stroke subtypes, the large-artery atherosclerosis and small-vessel subtypes were found to be more commonly inherited than the cardioembolic subtype (27). Few studies have separated ischemic stroke risk from that of ICH, probably because of the smaller frequency of the ICH stroke type and the difficulty in retrospectively obtaining this information. It appears that ICH in a first-degree relative increases a subject's odds by as much as 2- to 6-fold (28). SAH has a distinct clinical profile, and a family history of SAH has been associated with an increased risk for SAH of about 4-fold (29); because of this association, screening of first-degree relatives of patients with SAH is currently recommended (30). Evidence of a gene-environment interaction with smoking, another risk factor for SAH, also may exist for aneurysmal SAH (31).

## 123.4 SINGLE-GENE DISORDERS CAUSING STROKE

Single-gene disorders is a group of diseases caused by mutation in a single gene. In contrast, polygenic disorders are due to interaction of multiple gene mutations with lifestyle and environmental factors.

### 123.4.1 Ischemic Stroke

Ischemic stroke was divided into etiological categories according to TOAST criteria (14).

### 123.4.2 Small-Vessel Disease

#### 123.4.3 CADASIL – Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (NOTCH3 gene)

Cerebral arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)—Online Mendelian Inheritance in Man (OMIM) #125310 (<http://www.ncbi.nlm.nih.gov/omim/125310>, Accessed June 20, 2011)—is an autosomal dominant disorder. It affects small arterial vessels due to mutation in the NOTCH3 gene mapped on 19p13.2-p13.1.

From 1955, symptoms were recognized as Binswanger disease without hypertension (32), until 1991 when the relevant gene was mapped on chromosome 19 (33). Product of the NOTCH3 gene large type-1 transmembrane receptor (NOTCH3—N3) is mainly expressed in vascular smooth muscle cells and pericytes. Mature N3 consists of two independent domains: intracellular N3-ICD present in nucleus and responsible for gene expression regulation and extracellular N3-ECD. In CADASIL, mutations are present in N3-ECD within one of the 34 epidermal growth factor (EGF)-like repeat domains, each including six cysteine residues. All mutations, missense, deletion, and splice site, lead to an odd number of cysteine residues. Odd number of cysteines due to CADASIL mutations has been linked to multimerization of N3-ECD (34). Deposits of multimerized N3-ECD are components of the granular osmiophilic material pathognomonic for CADASIL on electron microscopy.

**123.4.3.1 Clinical Presentation.** CADASIL starts at the mean age of 45 years and leads to death in 10 to 25 years (35). The disease is characterized by five main symptoms: migraine with aura, subcortical ischemic events, mood disturbances, apathy, and cognitive impairment.

**Migraine with aura** occurs in approximately 20–40% of CADASIL patients—five times more than in general population. Frequency of migraine without aura is the same as in general population (32). Migraine is also a first presenting symptom in 34–36% of patients—usually before the age of 40 years (35). Symptoms, frequency, and severity of migraines vary across patients. Most attacks involve visual and sensory aura lasting 20–30 minutes, followed by prolonged headache. Atypical attacks with basilar, hemiplegic, or prolonged aura may be difficult to differentiate from ischemic episodes. Frequency of migraines may increase until first stroke, thereafter it cease or decrease.

**Subcortical ischemic events** represented by TIA and ischemic strokes affect up to 84% of patients with

CADASIL. In 70% of patients, these are the first CADASIL symptoms (35), occurring at the mean age of 49 years (32). Ischemic events are almost always subcortical and lacunar, affecting white matter and basal ganglia. Patients experience recurrent strokes, leading to progressive disability and pseudobulbar palsy.

**Mood disturbances and apathy** are the most common psychiatric manifestations of CADASIL. Mood disorders are present in 20% of patients with moderate depression, being the most common symptom. Other manifestations include aggression, agitation, delusional states, dysthymia, emotional lability, mania, paranoia, and schizophrenia-like symptoms (36). Apathy is present in 40% of patients with CADASIL and is associated positively with the load of white matter MRI lesions and with a decrease in quality of life (37).

**Cognitive impairment** is the second most frequent symptom in patients with CADASIL, rarely present at the onset of the disease. Frequency varies from 30 to 90% depending on patient's age (36). Cognitive deficit is slowly progressing, worsening after recurrent strokes.

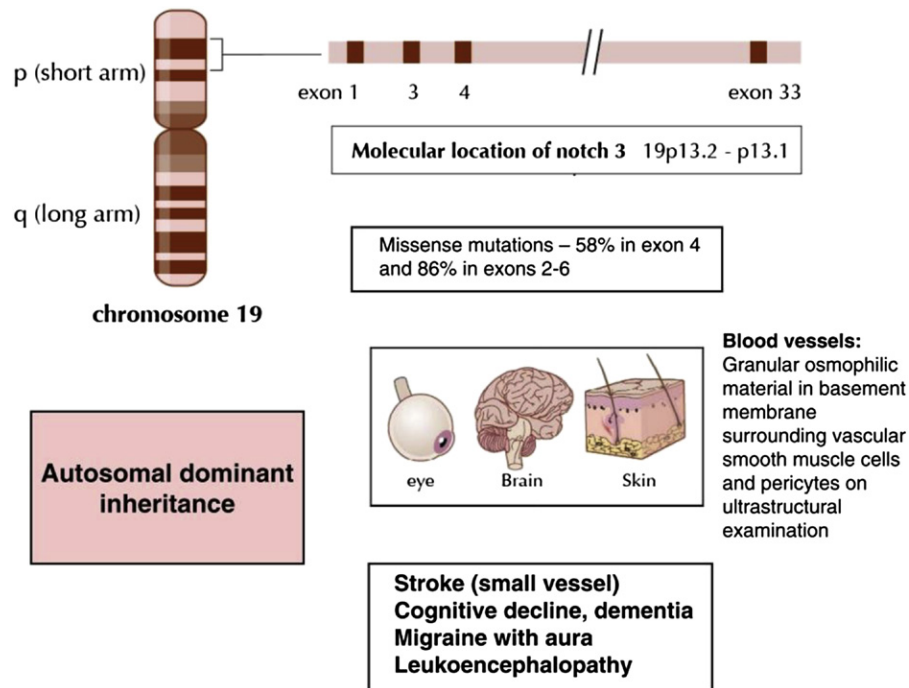

**Other clinical manifestations** include primary and secondary to stroke seizures 5–10% of patients, ocular symptoms, and ICHs (32) Figure 123-1.

**123.4.3.2 Diagnosis.** Genetic testing for the presence of EGF domain mutation in NOTCH3 gene is the only method to diagnose CADASIL. Due to the expensive and time-consuming procedure, patients should be preselected for genetic analysis based on diagnostic screening criteria and clinical presentation. MRI neuroimaging is the primary test that may be supported with the results from skin biopsy.

**123.4.3.3 Neuroimaging.** In most cases, MRI changes precede other common symptoms by 10–15 years appearing at the age of 30–35 years (32). Angiography is usually normal and is contraindicated due to increased risk of complications. MRI changes are present in T2- and T1-weighted images and fluid attenuated inversion recovery (FLAIR). Typically, symmetrical and diffuse MRI changes are present in periventricular areas and centrum semiovale. LACIs occur mostly in external capsule and anterior part of temporal lobes—location characteristic for CADASIL (32). Less frequently, changes may be present in the basal ganglia and thalamus, sporadically in the brainstem and corpus callosum (39). Focal microbleeds are commonly found in CADASIL patients (40).

**123.4.3.4 Skin biopsy.** Skin biopsies, based on two methods, were shown to be helpful in selecting patients for genetic testing. Samples stained with monoclonal antibodies specific for NOTCH3 showed high sensitivity (93%) and high specificity (100%) (41), whereas ultrastructural testing for extracellular deposits of granular osmiophilic material (GOM) in the tunica media was less sensitive (57%) and equally specific (100%) (42).

**123.4.3.5 Treatment.** So far, there is neither a specific nor a proven treatment for CADASIL. Separate treatment of CADASIL symptoms has also not been validated.

**FIGURE 123-1** Pathophysiology of CADASIL (38), by permission of Elsevier Inc. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), autosomal dominant disorder due to mutation in the Notch 3 gene. This gene is located on chromosome 19, on the p (short) arm, at 19p13.2 to p13.1. Notch 3 gene contains 33 exons; the majority of single-point or missense mutations occur on exons 2 to 6. There is an accumulation of osmophilic granules in smooth muscle of blood vessels throughout the vasculature, particularly in the brain, the retina, and the skin.

#### 123.4.4 CARASIL – Cerebral Autosomal Recessive Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (HTRA1)

Cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL)—OMIM #600142 (<http://omim.org/entry/600142>; Accessed June 20, 2011)—is an autosomal recessive disorder. It was named after Bowler and Hachinski in 1994 (43). Disease was diagnosed approximately in 50 Asian cases; except for two Chinese patients, all come from Japan (44). So far, there was only one Caucasian case of CARASIL carrying HTRA1 gene nonsense mutation (44). Disease affects small arterial vessels due to mutations in the HTRA1 gene mapped on chromosome 10q25.3-q26.2 (45). HTRA1 gene codes for HtrA serine peptidase/protease 1 (HTRA1) that represses signaling by transforming growth factor (TGF)- $\beta$  family members (46). Genome-wide linkage analysis in six consanguineous Japanese families with CARASIL identified 45 mutations in HTRA1 gene. In the case of a mutation, protein fails to repress TGF- $\beta$ , and the amount of TGF- $\beta$  is increased in the media of cerebral small arteries (45). As a result, intense arteriosclerosis is present mainly in the small penetrating arteries of the basal ganglia and cerebral white matter. Different than CADASIL, there are no GOM deposits of amyloid in the tunica media (46).

**123.4.4.1 Clinical Presentation.** Cerebral onset of CARASIL is between 20 and 45 years of age, with the

mean age of 32 (46). Duration of life ranges from 10 to 20 years; however, patients become bed-ridden within 10 years of onset (45). The disease is characterized by four main symptoms: ischemic stroke or stepwise deterioration; cognitive deficits; orthopedic complications; and alopecia (premature baldness).

**123.4.4.2 Ischemic Stroke or Stepwise Deterioration.** Characteristic lacunar strokes localized in basal ganglia and brainstem are present in 50% of the patients. Remaining patients develop stepwise deterioration, pseudobulbar palsy, pyramidal and extrapyramidal signs and gait disturbances (46).

**123.4.4.3 Cognitive Deficits.** Cognitive deficits occur in almost all CARASIL patients developing dementia by the age of 30–40 years. Symptoms that may occur include: forgetfulness, dyscalculia, time disorientation, personality changes, emotional incontinence, severe memory dysfunction, and finally abulia and akinetic mutism (46). Focal signs like aphasia or apraxia and abnormal behavior were not seen (46).

**123.4.4.4 Orthopedic Complications.** 80% of CARASIL cases develop acute middle to lower back pain. Spondylosis deformans or disk degeneration occurs, based on magnetic resonance imaging (MRI) and X-ray imaging, in cervical and/or thoracolumbar spine (46). Other orthopedic complications include osseous structures like kyphosis, ossification of intraspinal canal ligaments, deformity of the elbows, and arthropathy of the knee joints (47).

**123.4.4.5 Alopecia.** Hair loss present in 90% of the patients starts as early as adolescence and is limited to the head (46). Alopecia is less prominent but also present in affected women (47).

**123.4.4.6 Diagnosis.** Patients presenting with CARASIL's characteristic symptoms, lacunar strokes and white matter changes and cognitive deficits, alopecia and spondylosis, should be tested for HTRA1 gene mutations to confirm the diagnosis. Differential diagnosis should include Binswanger disease, angiitis of the central nervous system (CNS), CADASIL, chronic progressive multiple sclerosis, and leukodystrophies with dermatologic or skeletal disorders (46).

**123.4.4.7 Treatment.** At present, there is neither specific treatment of CARASIL itself nor its symptoms.

### 123.4.5 RVCL – Retinal Vasculopathy with Cerebral Leukodystrophy (TRESX1)

Retinal vasculopathy with cerebral leukodystrophy—RVCL—OMIM#192315 (<http://omim.org/entry/192315>; Accessed June 20, 2011)—is an autosomal dominant disease caused by mutations in TRESX1 gene on chromosome 3p21. Since 2007, RVCL encompasses three diseases—cerebroretinal vasculopathy (CRV), hereditary vascular retinopathy (HVR), and hereditary endotheliopathy with retinopathy and stroke (HERNS). Although clinical symptoms differ in the pathomechanisms of those three diseases, genetic mutations are the same (48). The TRESX1 gene codes for 3' > 5' DNA exonuclease. Mutations are present in C-terminus of TRESX1 gene and cause frame shift. Gene product retains exonuclease activity but loses normal perinuclear localization (48).

**123.4.5.1 Clinical Presentation.** RVCL ranges from 30 to 50 years of age, and death occurs within 5–10 years from the symptoms onset (49). Features commonly noted in patients with RVCL include neurological and ophthalmological manifestations. Other organs may also be involved and appear as renal impairment, proteinuria, hematuria, micronodular cirrhosis, gastrointestinal bleeding, anemia, and Reynaud's phenomenon.

**123.4.5.1.1 Neurological Manifestations.** A neurological manifestation encompasses clinical, radiological, and pathological changes. Strokes are usually localized in deep white matter and often resemble tumors due to irregular shape, mass effect, and edema. Other manifestations include seizures, migraine-like headaches, motor/sensory/cerebellar deficits, and psychiatric disturbances (50). Localized necrotic changes in the walls of the vessels may resemble obliterative vasculopathy.

**123.4.5.1.2 Ophthalmological Manifestations.** Progressive visual loss is the main feature of RVCL. Predominantly changes occur around macula. Loss of vision is secondary to retinopathy, microaneurysms with telangiectasia, and capillary dropout.

**123.4.5.2 Diagnosis.** Genetic screening for TRESX1 mutation will be positive and negative for mutations in NOTCH3 and HTRA1 genes.

**123.4.5.3 Treatment.** There is no specific treatment for RVCL.

### 123.4.6 Large-artery disease

**123.4.6.1 EDS IV – Ehlers–Danlos Syndrome Type IV (COL3A1).** Ehlers–Danlos Syndrome type IV (EDS IV)—OMIM#130050 (<http://omim.org/entry/130050>; Accessed June 20, 2011)—is an autosomal dominant disease. EDS IV is the vascular type, one of the six types of Ehlers–Danlos Syndrome (51). Disease is caused by mutation in type III collagen (COL3A1) gene on chromosome 2q31 (52). Mutations in COL3A1 are responsible for the structural defects in the protein pro  $\alpha$  1(III) chain of collagen type III. Presence of at least two major symptoms is indicative of the diagnosis; however, laboratory tests are needed. Four major diagnostic criteria include 1) thin and translucent skin, 2) fragility or rupture of arteries, uterine or intestines, 3) extensive bruising, and 4) characteristic facial appearance (51).

**123.4.6.1.1 Clinical Presentation.** Major clinical manifestations are seen in most patients by the age of 40 years, and median life span reaches 48 years (52). Vascular type is characterized by the highest mortality among other EDS types, high pregnant-related complications, fragile vessel prone to rupture joint hypermobility dermatological manifestations, and gastrointestinal complications.

Dermatological manifestations are usually the earliest in EDS IV. Vascular complications are leading causes of death with cerebrovascular events represented by stroke in young age, carotid–cavernous fistula, dissection of extracranial and intracranial segments of the vertebral and carotid arteries and aneurysms (53). In EDS IV, due to high complication rate, arteriography is not recommended (53).

**123.4.6.1.2 Diagnosis.** In addition to the presence of at least two major diagnostic criteria, abnormal structure of COL3A1 protein or identification of COL3A1 gene mutations is required to confirm the diagnosis (52).

**123.4.6.1.3 Treatment.** In EDS IV, there is no specific treatment, and medical interventions are limited to symptomatic treatment.

### 123.4.7 PXE – Pseudoxanthoma Elasticum (ABCC6)

Pseudoxanthoma elasticum (PXE)—OMIM #264800 (<http://omim.org/entry/264800>; Accessed June 20, 2011)—is an autosomal recessive disease affecting connective tissue. Disease is an effect of the mutation in ABCC6 gene on chromosome 16p13.11. Polymorphisms in xylosyltransferase genes XYLT1 and XYLT2 may modify severity of PXE. The prevalence is estimated to be about one in

25,000 to 100,000, with high variability both in the age of onset and in the severity of organ involvement. The disease primarily affects the skin, retina, and cardiovascular system. PXE is characterized pathologically by high elastic fiber mineralization (elastorrhexia), resulting in increased rate of elastin synthesis and degradation (54).

**123.4.7.1 Clinical Presentation.** The skin is the first affected organ. Yellow papules of 1 to 5 mm are the primary skin lesions. They are typically located on the neck and in flexural surfaces. Mucosal, genital, and navel area lesions are found less frequently.

The eye contains thin layer of elastic tissue called Bruch's membrane, located between the retinal pigment epithelium and the choriocapillaris. Elastic fiber alterations result in angioid streaks, characteristic for PXE. Other ocular manifestations—less specific for PXE—include appearance of 'peau d'orange, drusen, and comet-like streaks.

**Cardiovascular system** complications occur due to the changes in elastic fiber-rich arterial wall. Slowly progressing segmental arterial narrowing affects small- and medium-size arteries. Cardiovascular manifestations of PXE may be further divided in to the occlusive arterial disease and mucosal bleeding. Most commonly observed are coronary artery disease, arterial hypertension, restrictive cardiomyopathy, sudden cardiac failure, and gastrointestinal hemorrhages (55).

**Neurological complications** in PXE are mainly expressed by increased incidence of ischemic strokes due to small-vessel disease (56). ICH has also been reported in few PXE patients (57). However, IA has not been found in any of 100 PXE patients studied by Berg and colleagues (56).

**123.4.7.2 Diagnosis and Treatment.** Presence of angioid streaks in eye examination and dermal elastorrhexia (with or without clinically visible skin changes) represent the minimum criteria to diagnose PXE. Occurrence of ABCC6 gene mutation in one of the 31 exons confirms the diagnosis (55).

There is no specific treatment; however, antiplatelet drugs, high blood pressure, and contact sports should be avoided. Symptomatic treatments include retinal laser treatment and photodynamic therapy and valvular surgery in selected cases (57).

## 123.4.8 Small-Vessel Disease and Large-Artery Disease

**123.4.8.1 FD – Fabry Disease (GLA).** Fabry Disease (FB)—OMIM# 301500 (<http://omim.org/entry/301500>; Accessed June 20, 2011)—is an X-linked congenital dysfunction of glycosphingolipid (GSL) catabolism subsequent to deficient or absent activity of the lysosomal enzyme alpha-galactosidase A ( $\alpha$ -gal A) coded by gene *GLA* located on chromosome Xq22.1.  $\alpha$ -gal A activity in FD patients is usually lower than 1%, whereas the symptoms of enzyme deficiency are present below the level of 5–10% (58). Defects in  $\alpha$ -gal A impair its ability to

degrade membrane GSL, especially globotriaosylceramide (Gb3), which accumulates in various tissues throughout the body (59). Gb3 is found in all parts of blood vessel wall, in Schwann cells, dorsal root ganglia and in CNS neurons, leading to organ dysfunction (60).

Polymorphisms in genes, coding for interleukin-6, endothelial nitric oxide synthase, factor V and protein Z, affect the phenotypic expression of single-gene disorder in FD probably due to protein interactions (60).

The incidence of FB is estimated at one in 55000 male births (58); however, results from a newborn screening study by Spada et al. estimate higher rate of FD incidence falling between one in 3,100 and one in 4,600 individuals (61).

Some patients with residual  $\alpha$ -gal A activity develop a variant of the disease in which they develop only cardiac disease, specifically left ventricular hypertrophy, with or without renal failure, in the sixth decade of life (62). Although FB is an X-linked disease, it also affects females. Some woman may develop significant life-threatening conditions, requiring medical treatment and intervention (63).

**123.4.8.2 Clinical Presentation.** Major clinical manifestations develop from childhood until third decade in most cases. Median life span is decreased by 15–20 years (58). Clinical onset is characterized by painful burning sensations in the hands and feet (acroparesthesias), typical skin lesions (angiokeratomas), hypohidrosis, and corneal opacities. Further stages of the disease lead to the renal failure and vascular disease of the heart and the brain, with premature death in the fourth and fifth decades of life. Late-onset variants start from the sixth decade, and patients develop renal and/or cardiac disease without other neurologic symptoms. Based on results from Fabry Outcome Survey (64), neurologic symptoms were the most frequent, affecting 75% of males and 61% of females. Renal failure was present in 19% of males and 3% of females. Cardiac manifestations were recorded in 60% of males and in 50% of females. Cerebrovascular events occurred in 25% of males and 21% of females, and stroke was present in 5% of females and in 9% of males.

**123.4.8.2.1 Pain and Skin Lesions.** Neuropathic burning pain (acroparesthesia) usually involves hands and feet. It may be transient or may persist for several hours. The acroparesthesia is typically resistant to treatment with conventional analgesics and may require narcotic analgesics, phenytoin, amitriptyline, or gabapentin or combinations of these drugs (65). The pain is supposed to be caused by lysosomal accumulation of GSL in peripheral nerves, dorsal root ganglia, and the spinal cord and atrophy of the small, unmyelinated nerves involved in pain and temperature sensation (58).

FD is characteristic of angiokeratomas—vascular lesions characterized by thin-walled vessels beneath a hyperkeratotic epidermis. Skin lesions are usually located in periumbilical, scrotum, and penis areas (58) **Figure 123-2.**

**FIGURE 123-2** Umbilical (a) and thigh (b) angiokeratomas—vascular lesions characteristic for Fabry Disease. Image courtesy of M. Podolec-Rubis, MD and K. Podolec, MD (Department of Dermatology UJ Medical College).

**123.4.8.2.2 Impaired Renal Function and Cardiac Changes.** Renal failure occurs in midadulthood; the first indication is often isosthenuria, followed by proteinuria and gradual decline in glomerular filtration rate over time, leading to end-stage renal failure (66).

Cardiac complications of FD may include cardiac arrhythmias and conduction defects developed in the first two decades of life—progressive left ventricular hypertrophy, aggravated by arterial hypertension, which is followed by progressive impairment of diastolic filling that leads to decreased cardiac output and early death (58).

**123.4.8.2.3 Neurological Changes.** Population studies estimate that FD is responsible for 1.2% of cryptogenic strokes in patients younger than 55 years, and women are more likely to be affected than men (27% vs 12%) (67). Stroke may result from either cardiac or vascular factors and may cause both large- and small-vessel diseases. The large vessels dilate, resulting in dolichoectatic changes characteristic for FD. Subsequent flow stagnation increases the risk of artery-to-artery embolism and vessel thrombosis. These changes are found more frequently in the posterior circulation

(60). Stenosis in small arterial vessels is caused by gradual accumulation of GSL in endothelial and vascular smooth muscle cells (67).

**123.4.8.3 Diagnosis.** FD may be diagnosed based on the direct measurement of  $\alpha$ -gal activity in leukocytes or plasma in all except heterozygotic patients. In those subjects, gene sequencing and genetic linkage studies may be necessary (60).

**123.4.8.4 Treatment.** Treatment with  $\alpha$ -gal enzyme replacement therapy (ERT), approved by the US Food and Drug Administration in 2003, results in the reduction in the amount of vascular endothelial GSL deposits. ERT decreased the progression and severity of the changes observed in kidney, heart, skin, and liver. Unfortunately, ERT treatment did not change the incidence of stroke and other vasculopathic manifestations of the disease (67). Therefore, the use of antiplatelet and antihypertensive treatment is necessary to prevent secondary and primary strokes (60).

**123.4.8.5 Homocystinuria (CBS).** Homocystinuria indicates an increased urinary excretion of the oxidized form of homocysteine, homocystine. Classic homocystinuria—OMIM#236200 (<http://omim.org/entry/236200>; Accessed June 20, 2011)—is an autosomal recessive metabolic disorder caused by mutation in the gene encoding cystathionine beta-synthase (CBS) located on chromosome 21q22.3. The CBS gene has been both cloned and sequenced, revealing more than 140 mutations (68).

Homocystinuria is characterized by elevated levels of plasma. Usually, plasma homocysteine concentrations rises above 100 mmol/l, which is around 10-fold higher than normal (69). Homocysteine level elevation with a normal methionine level may be caused by metabolic errors that affect the conversion of homocysteine to methionine, such as methylene tetrahydrofolate reductase deficiency and disorders of cobalamin (vitamin B12) metabolism. The mechanism by which elevated homocysteine concentrations result in clinical manifestations remains unclear, although it has been shown to directly damage endothelium and promote smooth muscle cell proliferation (69).

The incidence of homocystinuria differs across countries and is estimated from 1:58,000 to 1:1,000,000, with overall rate of 1:344,000 (68). Clinically, two equally prevalent phenotypes have been described: a milder pyridoxal phosphate (vitamin B6), responsive form, and a more severe pyridoxal phosphate, nonresponsive form.

**123.4.8.6 Clinical Presentation.** The most common type homocystinuria type I is characterized by intellectual disability, lens dislocation, skeletal abnormalities, and thrombotic vascular disease due to a deficiency of the enzyme cystathionine synthase. Homocystinuria may also be due to defects in methyl cobalamin formation, which are specific for homocystinuria type II characterized by the triad of megaloblastic anemia, homocystinuria, and hypomethioninemia. Homocystinuria type III is a result of the deficiency of the enzyme methyltetrahydrofolate

reductase. Type III is characterized by homocystinuria and homocystinemia with low- or normal-blood methionine levels (70).

Homocystinuria can cause stroke through atherosclerosis, thromboembolism, small-vessel disease, and arterial dissection. Cerebrovascular events represent around 30% of thromboembolic complications (71).

**123.4.8.7 Diagnosis and Treatment.** The diagnosis of homocystinuria is based on clinical symptoms and laboratory studies. Plasma tests usually reveal hyperhomocystinemia, hypermethioninemia, and hypocystinemia, and the urinary excretion of methionine, homocysteine, and its oxidized form (homocystine) is elevated. Cultured fibroblasts, amniotic fluid, and chorionic villi cells are used to evaluate the activity of cystathionine synthase activity (72).

Treatment in hypocystinemia is aimed at lowering the plasma level of homocysteine—possibly to the normal values. Patients must adhere to a methionine-restricted diet. Roughly 50% of them respond to pyridoxine (vitamin B6). In addition, folate, betaine, and vitamin B12 are used to promote metabolism of homocysteine to methionine (72). Dietary supplementation with folic acid lowers plasma homocysteine concentrations by about 25%. Additional B-vitamin lowers homocysteine by about 10 to 15% (73).

## 123.4.9 Cardioembolic Stroke

**123.4.9.1 MS – Marfan Syndrome (FBN1).** Marfan Syndrome (MS)—OMIM#154700 (<http://omim.org/entry/154700>; Accessed June 20, 2011)—first described by Antoine-Bernard Marfan in 1986 is an autosomal dominant disorder of connective tissue caused by heterozygous mutation in fibrillin-1 gene (*FBN1*) located on chromosome 15q21.1. Main manifestations of MS involve cardiovascular system, eyes, skeleton, pulmonary system, skin, and dural sac. Family history is not conclusive in 27% of cases due to sporadic de novo *FBN1* gene mutations (74). Both hereditary and new mutations in *FBN1* gene lead to abnormal protein folding and enhanced proteolytic degradation. Mutant protein boosts matrix metalloproteinase (MMP) 2 and 9 activity and interferes with TGF  $\beta$  (TGF $\beta$ ) pathway. Recent evidences show that both abnormal TGF $\beta$  pathway and mutations in *TGFBR1* and *TGFBR2* genes may lead to Marfan-like phenotypes including Marfan syndrome II and Loeys-Dietz aortic aneurysm syndrome.

### 123.4.9.2 Clinical Presentation.

**123.4.9.2.1 General Complications.** Clinical characteristics of MS include tall stature, arm span higher than patient's height, reduced upper-to-lower body segment ratio, pectus carinatum or excavatum, ectopia lentis, scoliosis, mitral valve prolapse, aortic root dilatation, and aortic dissection (74).

**123.4.9.2.2 Neurological Complications.** In the largest retrospective study of MS patients by Wityk et al.

(75), neurovascular complications were found in 3.5% of patients. TIA was the most common complication, and cardiac source of embolism was found in 77% of all ischemic events. Neither cerebral artery dissection nor intracranial aneurysms (IA) were found in any of the studied patients. Another two studies by Conway and colleagues—firstly, found no statistical difference in the prevalence of IA between MS patients and general population (76); secondly, found no MS patients among 710 neurosurgical patients treated for IA (77).

**123.4.9.3 Diagnosis.** One of 500 so far discovered mutations in *FBN1* gene spanning 235 kb may occur in any of 65 exons, making the genetic testing costly and time consuming (78). Therefore, according to revised Ghent criteria, diagnosis is established primarily on clinical characteristics and family history (79). Personal or familial history of thoracic aortic aneurysm in tall, thin patients optionally with scoliosis, arachondactyly should always be suspected of MS.

## 123.4.10 Familial Cardiomyopathies and Familial Arrhythmias

Cardioembolic stroke and TIA are common complications of all types of cardiomyopathy, with AF being the main cause. Cardiomyopathies are classified according to their morphological characteristics as hypertrophic (HCM), dilated (DCM), arrhythmogenic right ventricular (ARVC), and restrictive cardiomyopathy (RCM). A genetic cause has been shown in significant number of patients: HCM (50%), DCM (35%), and ARVC (30%) (80). Cardiac dysrhythmias may be divided to supraventricular and ventricular. Dysrhythmias has been linked to number of genes and chromosomal loci. AF has been extensively studied and was mapped to four genes and nine chromosomal loci (81). In a largest study on 900 patients with hypertrophic cardiomyopathy by Maron et al. (82), 57 (6%) experienced thromboembolic event. Six of them were due to hemorrhagic stroke or brain tumor; Ischemic stroke occurred in 44 patients; 70% out of the remaining 51 with nonhemorrhagic thromboembolic event. Cardioembolic etiology of ischemic stroke was definite in eight cases and probable in 31, all of them had AF.

## 123.4.11 Other causes

**123.4.11.1 MELAS – Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke (A3243G).** MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes syndrome)—OMIM# 540000 (<http://omim.org/entry/540000>; Accessed June 20, 2011)—can be caused by mutation in several mitochondrial genes, including *MTTL1*, *MTTQ*, *MTTH*, *MTTK*, *MTTC*, *MTTS1*, *MTND1*, *MTND5*, *MTND6*, and *MTTS2*. Mitochondrial (mt) DNA is inherited exclusively from the mother (maternally

inheritance). The most common mtDNA mutation—A-to-G transition at nucleotide 3243—is present in 80% of MELAS patients (67). A3243G mutation is in the tRNA—leucine (UUR) gene, associated with respiratory chain complex I deficiency (67). The prevalence of the A3243G mutation varies across different population—it is estimated to be 7.59 per 100 000 persons in North East England, 16.3 per 100 000 in Northern Finland, and 236 per 100 000 in Australia (83).

Although the etiology of MELAS is not completely understood, there is likely a role for mitochondrial angiopathy, vascular dysfunction, and hyperemia, as well as mitochondrial-mediated cytopathic mechanisms, resulting in energy failure. Neuronal hyperexcitability may also play a role (84).

**123.4.11.1.1 Clinical Presentation.** Normal early development, followed by stroke-like episodes (before the age of 40 years), mitochondrial encephalomyopathy, and lactic acidosis, is typical for MELAS. Other clinical manifestations of MELAS may include exercise intolerance, short stature, central and peripheral nervous system involvement, hearing loss, and eye, heart, and gastrointestinal complications with accompanying DM (67).

CNS manifestations include stroke-like episodes, seizures, encephalopathy or dementia, headache, and elevated level of proteins in cerebrospinal fluid. Peripheral nervous system manifestations are represented by myopathy and peripheral neuropathy. The etiology of stroke-like lesions is not yet understood. The lesions have predilection to the posterior areas of the brain and may not follow arterial territory distribution (67).

**123.4.11.1.2 Diagnosis and Treatment.** Due to unequal load of mutated mtDNA, its content varies across different tissues, and genetic tests are not always conclusive. Sue et al. compared the detection rates for A3243G point mutation in muscle, blood, and hair follicles and found that in 50% mutation was absent in blood (85). Therefore, clinical symptoms, a key factor in the MELAS diagnosis, supported by laboratory tests, confirmed by biopsy and genetic studies are all essential in the diagnostic workup. Patients usually have increased lactate and pyruvate levels in serum and cerebrospinal fluid, and elevated lactate to pyruvate ratio. Muscle biopsy reveals typical ragged-red fibers (86).

Recently Janssen et al. presented a new method to diagnose MELAS—the mitochondrial energy-generating system (MEGS). MEGS as an indicator for the overall mitochondrial function related to energy production showed a great capacity for detection of subtle mitochondrial dysfunction (83). This method may be very useful in diagnosing patients with rare or new mitochondrial DNA mutations, and with low mutation loads.

Several treatment approaches have been tested to treat MELAS patients so far. Coenzyme Q10 and its synthetic analog Idebenone have been used to improve electron transfer in the mitochondrial respiratory chain. Their role in MELAS remains to be proven (67). Clinical

trial with another agent, dichloroacetate, was terminated earlier owing to frequent peripheral nerve toxicity (87). Finally, treatment with L-arginine (L-arg) shortly after the onset of stroke-like episodes improved patient's outcome and normalized the concentration of lactate and pyruvate (88).

### 123.4.12 NF 1 – Neurofibromatosis type I(NF-1)

Neurofibromatosis type I (NF1)—OMIM# 162200 (<http://omim.org/entry/162200>; Accessed June 20, 2011)—also known as von Recklinghausen disease is an autosomal dominant disorder caused by mutation in the neurofibromin gene (NF1) on chromosome 17q11.2. New mutations are very common, since 50% of patients are the first to be affected in the family (89). The NF1 gene codes for neurofibromin, a protein that is highly expressed in the nervous system. It functions as a tumor suppressor, and therefore, its loss leads to development of benign and malignant tumors (89). NF1 is approximately one per 2500 to 3000 individuals (90). NF1 decreases mean and median ages at death from 70.1 and 74 years to 54.4 and 59 years, respectively (91).

**123.4.12.1 Clinical Presentation.** Clinical features of NF1 encompasses café-au-lait spots, intertriginous freckling, and Lisch nodules, cutaneous, subcutaneous, and plexiform neurofibromas, macrocephaly, optic glioma, and other neoplasms (92). Based on the most common clinical features, the National Institutes of Health Consensus Development Conference formulated the diagnostic criteria for NF1 (93) (Table 123-2).

Reports on the incidence of neurological complication vary among authors, from 2.5% according to Roser et al. (94) to 20% and 26%, respectively; according to Griffiths et al. (95) and Hsieh et al. (96) Epilepsy (8.7%) and cerebral infarction (7.2%) are the most common neurological complications (96).

### 123.4.13 Ischemic and Hemorrhagic Stroke

**123.4.13.1 SCD – Sickle-Cell Disease (HBB).** Sickle-cell disease (SCD) refers to all the different genotypes that cause the characteristic clinical syndrome, whereas

**TABLE 123-2 NF1 Diagnostic Criteria (93)**

**At least two of the following criteria are required to diagnose NF1**

- Six or more café-au-lait macules (>0.5 cm in children or >1.5 cm in adults)
- Axillary or inguinal regions freckling
- At least 2 neurofibromas of any type or one plexiform fibroma
- Optic pathway glioma
- Two or more Lisch nodules (iris hamartomas)
- Osseous dysplasia
- A first-degree relative with NF1 diagnosed by these criteria

sickle-cell anemia—OMIM# 603903 (<http://omim.org/entry/6039030>; Accessed June 20, 2011)—represents the most common form of SCD, which is the result of the mutation in beta globin (*HBB*) gene located on chromosome 11p15.4. The most common type of sickle-cell disease is the homozygosity for the  $\beta$ S allele (HbS), and the remaining types include hemoglobin SC disease (HbSC disease) with coinheritance of the  $\beta$ S and  $\beta$ C alleles and HbS/ $\beta$ -thalassemia due to coinheritance of  $\beta$ S with a  $\beta$ -thalassemia allele (97).

HbS is caused by a T>A mutation in the  $\beta$ -globin gene in which the 17th codon is changed from thymine to adenine and the sixth amino acid in the  $\beta$ -globin chain becomes valine instead of glutamic acid (98). Mutant protein causes  $\beta$  globin chains to crystalize, resulting in a sickled appearance. Changes disrupt erythrocyte architecture and flexibility and promote cellular dehydration with physical and oxidative cellular stress (98). The disease severity is determinant by the rate and extent of HbS polymerization. Several mechanisms are involved in the pathophysiology of the SCD: vaso-occlusion with ischemia-reperfusion injury and hemolytic anemia causing hemoglobin and arginase-1 release into the circulation. Often triggered by inflammation, vaso-occlusion is caused by entrapment of erythrocytes and leucocytes in the microcirculation, causing vascular obstruction and tissue ischemia. Subsequent reperfusion of blood flow further promotes tissue injury (99). Hemolysis, also driven by HbS polymerization, causes anemia, fatigue, cholelithiasis, and, what was recently noticed, a progressive vasculopathy (97). Hemoglobin released from hemolyzed erythrocytes generates reactive oxygen species (ROS), such as the hydroxyl and superoxide radical. ROS are a potent scavenger of nitric oxide that disrupts endothelial cell function and induces the nitric oxide resistance (100), whereas free plasma arginase-1 transforms arginine—a nitric oxide substrate—into ornithine, decreasing bioavailability of nitric oxide in SCD patients (101).

In the largest autopsy study, Manici et al. (102) reviewed the cause of death in 306 SCD patients. The most common cause of death for all sickle variants and for all age groups was infection (33 to 48%) due to *Streptococcus pneumoniae* or *Haemophilus influenza*. Other causes of death included stroke (9.8%), complications of therapy (7%), splenic sequestration (6.6%), pulmonary emboli/thrombi (4.9%), renal failure (4.1%), pulmonary hypertension (2.9%), hepatic failure (0.8%), massive hemolysis/red cell aplasia (0.4%), and left ventricular failure (0.4%). In 40.8% of them, death was sudden and unexpected; in 28.4% occurred within 24 hours after presentation; and in 63.3% was associated with acute events (102).

**123.4.13.1.1 Clinical Presentation.** Sickle-cell disease phenotype is very complex, ranging from early childhood mortality to virtually no-symptom condition. Clinical features are a consequence of vaso-occlusion, hemolysis anemia, or infection.

Complications due to vaso-occlusion are complex and include painful episodes, stroke, acute chest pain, priapism, liver disease, splenic sequestration, spontaneous abortion, leg ulcers, osteonecrosis, and proliferative retinopathies renal insufficiency. Complications of hemolysis include anemia, cholelithiasis, and acute aplastic episodes. Infections are caused by *Streptococcus pneumoniae* in children and *Eserichia coli* in adults, causing sepsis, and both *Salmonella* and *Staphylococcus aureus* causing osteomyelitis (103).

Sickle-cell anemia is the most common cause of stroke in children. 11% of sickle-cell anemia patients suffer from stroke by 20 years and 24% by 45 years of age (104). Adams et al. (105) found a higher than previously expected (11 to 24% versus 6 to 8%) incidence of cerebral vascular events in the first 2 weeks of life of SCD patients. This finding reflects a large number of silent strokes. Ischemic stroke (54%) is the most common type of cerebrovascular accident, followed by hemorrhagic stroke (34%) and TIA (11%). The greatest risk of ischemic stroke is in the first two decades of life, whereas hemorrhagic stroke falls in the third decade (100).

**123.4.13.1.2 Diagnosis and Treatment.** All newborns are screened for sickle-cell disease in the US. Diagnosis is based on hemoglobin high-performance liquid chromatography (HPLC), electrophoresis, or isoelectric focusing. Transcranial Doppler ultrasound is a useful tool to screen for significantly narrowed vessels in high-risk children and adults. Genetic counseling requires genetic tests for globin gene mutations (106). Prenatal and antenatal tests are also available (103).

Hydroxycarbamide is a cytotoxic drug that increases the fetal hemoglobin (HbF) concentration, which inhibits HbS polymerization. Treatment decreases the frequency of painful episodes, acute chest syndrome, demand for blood transfusion, and admission of SCD patients to hospital. It may also protect against cerebrovascular events and decrease hypoxemia and proteinuria (97). Blood transfusion with ion chelators in case of chronically transfused patients with sickle-cell disease has an established role in SCD treatment. Repeated transfusions improve oxygen saturation and reduce red blood cell sickling (69). Introduced 30 years ago, bone marrow transplantation is the only potential cure for sickle-cell anemia; however, due to safety concerns, it is limited to HLA-compatible siblings (97).

## 123.4.14 MMD – Moyamoya Disease

Moyamoya disease (MMD) is an uncommon cerebrovascular disorder predominantly affecting East Asians. The disease was named after characteristic cerebral angiographic picture “moyamoya” what in Japanese means “something hazy like a puff of cigarette smoke, drifting in the air.” The pathogenesis of the disease remains to be discovered. Data from epidemiological studies indicate that infection in the head and neck might be implicated

**TABLE 123-3 Genetic Types of MMD (<http://omim.org/entry/252350>; Accessed June 20, 2011)**

Phenotype	Location	Phenotype MIM Number	Gene/Locus	Gene/Locus MIM Number
Moyamoya disease 1–MYMY1	3p26-p24.2	252350	Unknown	Unknown
Moyamoya disease 2–MYMY2	17q25.3	607151	<i>RNF213</i>	613768
Moyamoya disease 3–MYMY3	8q23	Unknown	Unknown	Unknown
Moyamoya disease 4–MYMY4	Xq28	300845	Unknown	Unknown
Moyamoya disease 5–MYMY5	10q23.31	614042	<i>ACTA2</i>	102620

in the development of MMD (107). Genetic factors also play an important role in MMD. Associations with loci on chromosomes 3, 8, 10, 17, and X have been described (Table 123-3). MMD inheritance pattern is polygenic or autosomal dominant with a low penetrance (108).

The incidence of MMD is highest in countries in East Asia; however, it is also present throughout the world in people of many ethnic groups. MMD onset peaks in two age groups: children who are approximately 5 years of age and adults in their mid-40s (109). There are nearly twice as many female patients as male patients (110).

MMD affects—usually bilaterally—terminal portions of the internal carotid vessels as well as cerebral vessels originating from the circle of Willis. In addition to the steno-occlusion, affected arteries show fibrocellular thickening of the intima, an irregular folding of the internal elastic lamina, and reduction of the media. The perforating arteries in subcortical areas are either dilated (in children) or stenotic with thick walls (in adults). These changes predispose to microaneurysmal formation and subsequent intracerebral and intraventricular hemorrhage (111).

**123.4.14.1 Clinical Presentation.** Symptoms may be divided in two main etiological categories: related to ischemia and related to hemorrhage. Ischemic symptoms are more common in children and comprise ischemic stroke and TIA. Ischemia may cause hemiparesis, dysarthria, aphasia, and cognitive impairment. Seizures, visual deficits, syncope, or personality changes are less common in ischemic etiology. Hemorrhage is common in adults (50%); however, it was also noted in children (112). It may be located in intraventricular, intraparenchymal, or subarachnoid space. Hemorrhage is either due to rupture of dilated, fragile affected vessels, or rupture of saccular aneurysms in the circle of Willis (107). Rare symptom include seizures, migraine-like headache, choreiform movements due to basal ganglia involvement and occasionally present ophthalmologic findings like “morning glory disk” (110).

**123.4.14.2 Diagnosis and Treatment.** Diagnosis of patients suspected of MMD is based on imaging studies. Research committee on Spontaneous Occlusions of the Circle of Willis of the Ministry of Health and Welfare of Japan published revised diagnostic criteria (Table 123-4). Additional useful diagnostic tests include electroencephalography (EEG) and cerebral blood-flow studies.

So far, there is no treatment that reverses the primary disease process; however, symptomatic treatment focused on improvement of cerebral blood flow reduces the frequency of MMD symptoms (107). Medical therapy—antiplatelet and less frequently anticoagulant—is used mainly in children due to very low percentage of hemorrhagic strokes, whereas surgical treatment is used both in young and adult patients. Since the external carotid artery is spared in MMD, direct, indirect, and combined surgical bypass operations are performed to improve the cerebral blood flow (110).

#### 123.4.15 Collagen Type IV (COL4A1 Gene and COL4A2 Gene)

The collagen IV molecule is a heterotrimer composed of two alpha-1 chains and one alpha-2 chain. *COL4A1* OMIM# 120130 and *COL4A2* OMIM# 120090 genes are coding for alpha-1 chain and alpha-2 chain of type IV collagen respectively. They are associated together structurally and functionally with each other (<http://omim.org>; Accessed June 20, 2011). Both genes are located on chromosome 13q34 and are universally expressed in basement membranes during early stages of development (113). A number of mutations have been described for *COL4A1* gene (114) and recently also for *COL4A2* gene (115,116). In addition to porencephaly, infantile hemiplegia and hemorrhagic stroke *COL4A1* gene mutations induce cerebral small-vessel disease (117). Hemorrhagic strokes are usually associated with physical activity, trauma and anticoagulant therapy, whereas SVD was expressed as leukoaraiosis (63.5%), microbleeds (52.9%), lacunar infarction (13.5%), and dilated perivascular spaces (19.2%) (118). Based on results by Janne et al. (115), mutations in *COL4A2* gene contribute to sporadic cases of ICH, due to intracellular accumulation of gene product.

#### 123.4.16 Hemorrhagic Stroke

**123.4.16.1 CCM 1 to 3-Cerebral Cavernous Malformations (KRIT1, Malcavernin, PDCD10).** Cerebral cavernous malformations (CCM) are relatively common lesions occurring incidentally or in autosomal dominant fashion. The autosomal dominantly inherited type is caused by mutations in one of at least three

**TABLE 123-4 Diagnostic Criteria for MMD (107,112)**

1. Cerebral angiography findings:
  - a. Stenosis or occlusion at the terminal portion of the ICA and/or at the proximal portion of the ACAs and/or the MCAs.
  - b. Abnormal vascular networks in the vicinity of the occlusive or stenotic lesions in the arterial phase.
  - c. "a" and "b" are present bilaterally.
2. MRI and MRA findings:
  - a. MRA showing stenosis or occlusion at the terminal portion of the ICA and at the proximal portion of the ACAs and MCAs.
  - b. MRA showing an abnormal vascular network in the basal ganglia. Abnormal vascular network can also be diagnosed when more than 2 apparent flow voids are observed in one side of the basal ganglia on MRI.
  - c. (1) and (2) are observed bilaterally.
3. Elimination of the following conditions: arteriosclerosis, autoimmune disease, meningitis, brain neoplasm, Down syndrome, Recklinghausen disease, head trauma, irradiation to the head and other conditions (sickle-cell disease, tuberous sclerosis).
4. Pathological findings:
  - a. Intimal thickening with resulting stenosis or occlusion of the lumen usually observed on both sides, both in and around the terminal portion of the ICA. Lipid deposits are infrequently noted in the proliferating intima.
  - b. Stenosis of various degrees or occlusion associated with fibrocellular thickening of the intima, a waving of the internal elastic lamina, and an attenuation of the media is characteristic for ACAs, MCAs, and posterior communicating arteries, constituting the circle of Willis.
  - c. Perforators and anastomotic branches forming small vascular channels are frequently observed around the circle of Willis.
  - d. Presence of reticular conglomerates of small vessels is common in the pia mater.

Autopsy cases without cerebral angiography should refer to 4.

1. **Definite case:** adults, either 1 and 3 or 2 and 3; children, either 1-a and 1-b or 2-a and 2-b with sever stenosis at the terminal portion of the ICA on the opposite side.

2. **Probable case:** fulfills 3 and either 1-a and 1-b or 2-a and 2-b.

ICA- internal carotid artery, ACA- anterior cerebral artery, MCA- middle cerebral artery, MRI- magnetic resonance imaging, MRA- magnetic resonance angiography.

**TABLE 123-5 Genetic Types of CCM (<http://omim.org/entry/116860>; Accessed June 20, 2011)**

Phenotype	Location	Phenotype MIM Number	Gene/Locus	Gene/Locus MIM Number
CCM-1; Cerebral cavernous malformations-1	7q21.2	116860	<i>CCM1</i>	604214
CCM-2; Cerebral cavernous malformations-2	7p13	603284	<i>C7orf22</i>	607929
CCM-3; Cerebral cavernous malformations-3	3q26.1	603285	<i>PDCD10</i>	609118

genes *CCM-1*, *CCM-2* and *CCM-3* (Table 123-5). The prevalence of CCM has been estimated from 0.17 to 0.55 per 100000 in general population (119).

CCMs are slow-flow, sinusoid blood vessels, lacking smooth muscle cells and elastic lamina. They are lined with endothelial cells that do not have tight junctions, which make them prone to intracranial hemorrhage (120). Blood at various stages of thrombosis usually fills CCM vessels forming mulberry-like shapes. Even in the absence of obvious hemorrhage, all lesions are surrounded by the deposits of hemosiderin (119).

More than half of CCMs are familial (121). Multi-locus linkage analysis revealed that *CCM1* is present in 40%, *CCM2* in 20%, and *CCM3* in 40% of inherited cases. *CCM* genes products, respectively *CCM1/Krit1*, *CCM2/macaverinin*, and *CCM3/PDCD10*, are specifically expressed in endothelium, neurons, and astrocytes (121). Based on immunohistochemical staining, Pagenstecher and colleagues showed loss of expression of

*CCM*-coded proteins, limited only to endothelial cell within cavernous malformation. Additionally, their results demonstrated endothelial cell mosaicism within cavernous tissue (122).

**123.4.16.1.1 Clinical Presentation.** If not symptomatic (47% of cases), CCM presents typically with epileptic seizures (25%), intracranial hemorrhage (12%), or focal neurologic deficits including headaches (15%) (120). The hemorrhage rate in patients with CCM has been estimated to be 0.7%–4.2% (123). The five-year annual rates of hemorrhage among patients presenting with hemorrhage, with symptoms not related to hemorrhage and an incidental finding, were respectively 6.19%, 2.18%, and 0.33% (124). Risk of recurrent hemorrhage decreases over time from 19.8% in the first year to 5% in the fifth year (120).

**123.4.16.1.2 Diagnosis and Treatment.** MR imaging with T2-weighted gradient-echo imaging is currently the gold standard imaging technique for detecting both

sporadic and familial CCMs (125). Currently, surgical removal is the only treatment option in CCM. After careful patient selection, surgery significantly improves patient's neurological condition, from 5.9 NIHSS score after the first episode to 1.7 NIHSS score after 40 months postoperative follow-up (126). Experimental results have shown that mutations in two CCM (KRIT1 and OSM) genes cause RhoA activation. Treatment aimed at blocking activated RhoA may potentially stop the disease (127).

**123.4.16.2 HHT – Hereditary Hemorrhagic Telangiectasia (ENG, ACVRL1 and SMAD4).** Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant vascular dysplasia. Rendu, Osler, and Weber independently gave the original description of HHT in the nineteenth century, hence the eponymous Rendu–Osler–Weber syndrome. So far, based on the affected gene/locus, five types of HHT have been described. (Table 123-6). Telangiectasias are characterized by the presence of multiple arteriovenous malformations (AVMs) of different sizes. AVMs lack intervening capillaries that result in direct connections between arteries and veins (128). They are usually found in the skin, mucosa, and viscera.

Although the prevalence of HHT is estimated from one per 5000 to one per 10,000, it may be underdiagnosed due to variable phenotypes and diagnostic limitations (129).

Each of the genes in HHT1, HHT2 and JHPT encodes a protein involved in TGF- $\beta$  superfamily signaling. The genes within chromosomal regions in HHT3 and HHT4 types remain to be discovered. Endoglin (ENG)—HHT1—is expressed predominantly on endothelial cells, syncytiotrophoblasts, activated monocytes, and tissue macrophages. ENG is a coreceptor from the TGF- $\beta$  family and binds TGFB1 and TGFB3 proteins (128). Activin A receptor type II-like 1 (ACVRL1)—HHT2—codes for the activin receptor-like kinase (ALK) 1, which is a type I receptor from the TGF $\beta$  superfamily ligands. ALK1 is expressed on endothelial, lung, and

placental cells (128). MADH4—JHPT—encodes the transcription factor Smad4. Mutations in Smad4 cause juvenile polyposis/HHT syndrome by disturbing TGF / BMP pathway (128).

**123.4.16.2.1 Clinical Presentation.** Main HHT symptoms include epistaxis, telangiectasia, gastrointestinal (GI) bleeding, pulmonary AVM (PAVM), cerebral system HHT complications, and hepatic vascular abnormalities. The age of AVM development or AVM symptom onset varies and is organ-specific. AVMs in the brain are usually present at birth, whereas those in liver and in lungs develop or grow over time (128).

Nasal bleeding is the major manifestation of mucous telangiectases and, in HHT, is the main reason to seek medical attention. On average, epistaxis starts at the age of 12 years but may range from infancy to adulthood. It affects more than 95% of patients (130).

Telangiectases of the face, oral cavity, or hands develop as often as epistaxis, but later in life. One-third of affected patients develop telangiectases before the age of 20 years, with remaining two-thirds developing symptoms before the age of 40 years (131). The color of the telangiectases may range from pink to red, and the size may vary from pinhead-size lesions to larger, sometimes raised purple lesions. Telangiectases may be distinguished from petechiae and angiomas by blanching upon pressure and recurrent immediate refill (128).

GI bleeding due to AVM affects 15–45% of patients with HHT and begins after the age of 50 years. If prolonged, this can lead to anemia and the need for transfusion. Telangiectases usually develop in upper GI tract; however, other localizations are also possible (128).

Although 74% of HHT patients develop hepatic vascular abnormalities, only 8% are symptomatic (128). Three different types of vascular malformations may be observed in the liver: hepatic artery to hepatic veins, hepatic artery to portal veins, and portal veins to hepatic veins (130).

**TABLE 123-6 Genetic Types of HHT (<http://omim.org/entry/187300>; Accessed June 20, 2011)**

Phenotype	Location	Phenotype MIM Number	Gene/Locus	Gene/Locus MIM Number
Telangiectasia, hereditary hemorrhagic, type 1- HHT1	9q34.11	187300	ENG	131195

<sup>a</sup>The Genome Reference Consortium Human genome build 37 (GRCh37), from NCBI.

Prevalence of PAVMS ranges from 15 to 59%, depending on the method used for detection (128). Patients with ENG gene mutations seems to have higher incident of PAVMS compared with ACVRL1 mutation carriers (129). PAVMS frequently cause neurological complications. TIA, ischemic stroke or brain abscess were found in 30–40% of patients with PAVMs. Other pulmonary complications include massive hemoptysis or hemothorax and pulmonary hypertension (132).

AVMs may be found in the brain and less frequently in the spine; overall, CNS vessel malformation rate ranges from 10 to 23% in HHT patients (130). Based on a retrospective study, bleeding risk is approximately 0.5% per year (130). The wide spectrum of CNS symptoms includes headaches, acute or subacute hemorrhage, back pain, acute or progressive paraparesis/tetraparesis, sciatic pain, and sphincter disturbance.

**123.4.16.2.2 Diagnosis and Treatment.** The Curaçao criteria (Table 123-5) have been established for the HHT in 1999 (133) and are as follows: (1) spontaneous recurrent epistaxis; (2) multiple telangiectases at characteristic sites; (3) family history; and (4) visceral lesions. If at least three criteria are present, the diagnosis is definite. Diagnosis is possible or suspected if two criteria are present, and unlikely if less than two criteria are present. Mutations in *ACVRL1*, *ENG* and *MADH4* genes are found in 90% of definite HHT patients. Genetic tests are currently used to diagnose asymptomatic patients and to avoid complications (130).

Epistaxis may be treated surgically with steroids and with antifibrinolytic drugs. Cutaneous and labial telangiectases may be treated with laser therapy. GI treatments have not been successful, and transplantation is the only treatment option for hepatic involvement (130). Because lung and brain AVMs may cause serious complications, they should be treated before they become symptomatic. Screening for brain AVMs should first include contrast-enhanced MR imaging and, if necessary, should be evaluated with angiography. Surgery is the first brain AVM treatment option; however, due to difficult localization, this may not be possible. Therefore, in certain situation, surgery should be replaced by stereotactic radiosurgery or by embolization (130).

### 123.4.17 CAA – Cerebral Amyloid Angiopathies

Cerebral amyloid angiopathy (CAA) is a process of progressive pathological deposition of amyloid proteins in arterial and arteriole walls and less frequently in veins and capillaries of the CNS. Amyloid deposits damage the vessel wall and activate matrix metalloproteinases 2 and 9 (MMP-2 and MMP-9) (134). CAA may occur as sporadic, familial, or hereditary disease. Familial and hereditary forms of CAA are described in Table 123-7. Deposited pathologic proteins are products of large-protein proteolysis. The most common form of CAA is due to A $\beta$  deposition—product of amyloid precursor protein (APP) proteolysis. Other less common proteins include both ABri and ADan, which are products of amyloid Bri precursor protein (ABriPP) proteolysis, mutant cystatine C (Acys), mutated transthyretin (ATTR), mutated gelsolin (AGel) and disease-associated prion protein (PrP) (134). Based on A $\beta$  form of CAA, in initial stages, cerebrovascular amyloid appears around smooth muscle of tunica media and adventitia, then gradually infiltrates, and finally replaces the smooth muscle cells (135). CAA is generally assumed to be a risk factor for ICH, ischemic stroke, and white matter lesions. Nevertheless, in sporadic cases, CAA may not suffice to explain the incidence of hemorrhage (134).

### 123.5 CVT – CEREBRAL VENOUS THROMBOSIS (FVL, PROTHROMBIN)

Cerebral venous thrombosis (CVT) is a rare cause of stroke due to the thrombosis of the dural sinus and/or cerebral veins. CVT affects approximately 5 persons per million annually accounting for 0.5 to 1% of all strokes (19). CVT is more common (78%) in patients under 50 years of age (19). The acute phase of CVT-case fatality is around 4%, whereas overall death or dependency rate is around 15% (18).

There are multiple predisposing causes of CVT (Table 123-8). All are linked to the Virchow triad of alterations in blood flow, vascular endothelial injury, or alterations in the constitution of the blood. Other causes of CVT

**TABLE 123-8 CVT Risk Factors (19)**

Condition	Prevalence, %	OR (95% CI; p-value)
Prothrombotic conditions	34.1	NA
Protein C deficiency	N/A	11.1 (1.87 to 66.05; P=0.009)
Protein S deficiency	N/A	12.5 (1.45 to 107.29; P=0.03)
Antiphospholipid and anticardiolipin antibodies	5.9	8.8 (1.3 to 57.4; NA)
Mutation G20210A of factor II	N/A	9.3 (5.9 to 14.07)
Resistance to activated protein C and factor V Leiden		3.4 (2.3 to 5.1)
Hyperhomocysteinemia	4.5	4.6 (1.6 to 12.0; NA)
Pregnancy and puerperium	21	NA
Oral contraceptives	54.3	5.6 (4.0 to 7.9; NA)

N/A – not available.

can be divided into acquired and genetic risks. Main (18) acquired causes comprise antithrombin III, protein C, and protein S deficiency; antiphospholipid and anticardiolipin antibodies; hyperhomocysteinemia; pregnancy and puerperium; oral contraceptives and cancer (18).

The prevalence of thrombophilic symptoms in children with CVT varies between 10 and 78% (136). Both mutations in factor V Leiden gene (R506Q) due to resistance to activated protein C and prothrombin gene mutation (G20210A) causing a slight elevation of prothrombin level are independent CVT risk factors. While on oral contraceptive treatment, odds ratio for CVT is dramatically increased for G20210A mutation to 149.3 (95% CI 31.0 to 711.0) (19).

### 123.5.1 Clinical Presentation

The wide range of presenting symptoms may be classified into two main categories: (1) related to increased cranial pressure due to impaired venous drainage; and (2) related to focal brain injury due to venous ischemia/infarction or hemorrhage, with a number of patients presenting both mechanisms (19). The most frequent symptoms are headache, seizures, focal neurological deficits, altered consciousness, and papilledema, (18) all of which may be present isolated or in association with other symptoms.

### 123.5.2 Diagnosis and Treatment

Diagnosis of patients suspected of CVT is based on clinical suspicion and imaging confirmation that may be supported with selected laboratory tests. Laboratory tests include routine blood work to reveal potential prothrombotic conditions and a level of D-dimers (137). Noninvasive imaging modalities include CT, MRI, and ultrasound. CT Venography (CTV) and magnetic resonance venography (MRV) are most useful. Invasive diagnostic angiographic procedures comprise cerebral angiography and direct cerebral venography (19).

Anticoagulant therapy has been successfully introduced in CVT treatment in order to prevent thrombus growth, facilitate recanalization, and to prevent DVT. Both LMWH and UFH are safe and effective, with a

possible advantage of LMWH (19). Direct intrasinus thrombolytic techniques and mechanical therapies may be considered in three cases—first, if despite the use of anticoagulation clinical deterioration is present; second, if mass effect from a venous infarction occurs; and third, if ICH that causes intracranial hypertension is resistant to standard therapies (19).

## 123.6 GENOME-WIDE ASSOCIATION STUDIES AND GENOMICS

Advances in genetics and genomics may permit new insights. In recent genome-wide association studies, a number of single-nucleotide polymorphisms have been associated with specific stroke subtypes and major stroke-risk factors such as diabetes and AF, but these have yet to be replicated. Studies of messenger RNA expression have also shown promise for the development of genomic signatures for stroke classification.

## 123.7 SUMMARY

At present, the contribution of genetic factors to stroke etiology and risk is small, involving familial predisposition, a small number of monogenic disorders such as CADASIL—the prototype genetic disorder associated with stroke—and polymorphisms associated with cerebral venous thrombosis. Possible new associations are being explored in genome-wide association studies but no markers have yet emerged.

### Biographies

Dr Adamski has joined Dr Baird's group at the State University of New York (SUNY) Downstate Medical Center in 2008. He came from the Jagiellonian University Medical College in Cracow, Poland.

Dr Adamski received his medical degree and a Master of Science degree in Molecular Biology, and Biotechnology Biology from the Jagiellonian University Medical College in Cracow, Poland.

Dr Adamski's research interests are focused on genetic and immunological aspects of stroke. He studies both clinical and translational aspects of stroke.

Dr Baird has served as the Professor and Director of the Stroke Program at the State University of New York (SUNY) Downstate Medical Center since 2007. She came from the National Institutes of Health in Bethesda, MD, where she was chief of the Stroke Neuroscience Unit and Principal Investigator at the National Institute of Neurological Disorders and Stroke.

A Fellow of the Royal Australasian College of Physicians, Dr. Baird received her medical degree from the University of Melbourne, Australia, and a Master of Public Health from Harvard. After completing a Clinical Stroke Fellowship at Beth Israel Deaconess Medical Center and Harvard University in Boston, she joined the Neurology faculty at Harvard Medical School.

Dr. Baird lectures worldwide and has published widely. She has performed extensive clinical and translational research. She serves on the editorial boards of a number of medical journals. Dr. Baird is a Fellow of the American Heart Association/American Stroke Association, the Royal Australasian College of Physicians and a member of the American Academy of Neurology, the American Neurological Association, the New York State Neurological Society, and the Society for Neuroscience.

## Primary Tumors of the Nervous System

*Angel A Alvarez and Markus Bredel*

This article is a revision of the previous edition article by Daniel R Scoles, Asha Das, and Stefan M Pulst, volume 3, pp 2879–2894, © 2007, Elsevier Ltd.

### ABBREVIATIONS

ATM – Ataxia-telangiectasia mutated  
 EGFR – Epidermal growth factor receptor  
 NF-1 – Neurofibromatosis 1  
 NF- $\kappa$ B – Nuclear factor kappa-light-chain-enhancer of activated B cells  
 PDGF – Platelet-derived growth factor  
 PTCH1 – Protein patched homolog 1  
 PTEN – Phosphatase and tensin homolog  
 TP53 – Tumor protein 53  
 TSC – Tuberous sclerosis protein

### 124.1 INTRODUCTION

This chapter reviews the current knowledge about the molecular genetic alterations associated with the initiation and progression of the most common forms of primary nervous system tumors. These include glial tumors, primitive neuroectodermal tumors (PNETs), meningiomas, and schwannomas. We briefly review recent epidemiologic data and the present histopathologic classification of primary nervous system tumors. In addition, we discuss the hereditary syndromes predisposing to the development of tumors of the nervous system.

### 124.2 EPIDEMIOLOGY

Estimates of the incidences of the various tumors of the nervous system vary considerably depending on the source of data (1). Tumors of the central nervous system (CNS) are common and occur with an incidence of 6–16 per 100,000 (2). Consistent with this estimate, according to the Year 2000 Standard Statistical Report of the Central Brain Tumor Registry of the

United States (CBTRUS, [www.cbtrus.org](http://www.cbtrus.org)), the overall annual incidence rate for primary benign and malignant brain tumors in the United States is 14.1 cases per 100,000 (3). The relative incidence of CNS tumors is age dependent. Intracranial neoplasms represent the most common solid tumors in children younger than 15 years of age, among which primary tumors of the nervous system comprise nearly 20% of all cancers, making them the second most common form of childhood cancer next to leukemias (4). The incidence of primary brain tumors has apparently increased among the elderly population (2,5), even after correction for improved diagnostic methods (6).

### 124.3 CLASSIFICATION

There are multiple systems for the classification of brain tumors. Attempts are being made to revise classifications from a morphology-based approach identifying a “cell of origin” or “embryogenetic” phase to a more comprehensive approach incorporating molecular data (7). Applications of these approaches may help to validate some of the more recent classification concepts, such as the classification of embryonal tumors; however, many of the original terms are still in clinical use. For example, medulloblastoma was named after the presumed progenitor cell, the “medulloblast.” The newer classification systems should increase prognostic accuracy and may provide a basis for developing treatment strategies for specific tumor types.

Several different types of brain tumors can be distinguished based on classic morphologic criteria. Overall, the most common type of brain tumor is the glioma, which constitutes more than half of all brain tumors, followed by meningioma and schwannoma, which make up

20% and 10%, respectively. Of the rarer brain tumors only ependymoma and medulloblastoma are discussed.

The location and histologic type of brain tumors differ in children and in adults. In children, brain tumors occur most frequently in the posterior fossa. The most frequent tumor types are ependymoma, medulloblastoma, and astrocytic tumors, including spongioblastoma, cerebellar astrocytoma, and optic nerve glioma. In adults, the majority of tumors are supratentorial. Meningiomas and gliomas predominate.

The World Health Organization (WHO) has established a widely used grading system for classifying CNS tumor malignancy (8). This classification, based on histopathologic tumor typing, also has an optional WHO grading that ranges from WHO grade I (benign) to WHO grade IV (malignant). Tumors with minimal proliferative potential are classified as WHO grade I lesions. Such tumors include pilocytic astrocytomas, subependymomas, myxopapillary ependymomas of the cauda equina, a variety of neuronal and mixed neuronal/glia tumors, schwannomas, and most meningiomas. Tumors with lower mitotic activity and a tendency for recurrence are classified as WHO grade II. Grade II tumors include well-differentiated astrocytomas, oligodendrogliomas, mixed gliomas, and ependymomas. Neoplasms with histologic evidence of anaplasia, generally in the form of increased mitotic activity, increased cellularity, nuclear pleomorphism, and cellular anaplasia, are classified as WHO grade III. WHO grade IV is assigned to mitotically active and necrosis-prone highly malignant neoplasms. Typical examples include glioblastomas and PNETs (8).

The WHO classification presently is the standard classification system for CNS tumors. The general use of this classification provides a common morphologic baseline in neuro-oncology and greatly facilitates comparison of clinical and laboratory results from different institutions around the world. Gilles and colleagues (9) highlighted certain limitations of the WHO classification of childhood tumors for prognosis. They proposed a classification technique that simultaneously accounts for all reliably recognized histologic features.

A new classification system has emerged for glioblastomas based on extensive genomic analysis, revealing four distinct subtypes: classic, neural, proneural, and mesenchymal.

## 124.4 INHERITED TUMOR SYNDROMES PREDISPOSING TO CENTRAL NERVOUS SYSTEM TUMORS

Most brain tumors occur in a sporadic fashion. On rare occasions, however, brain tumors may occur as part of known inherited cancer syndromes (Table 124-1). Often, the germline mutations manifest themselves by the development of non-CNS malignancies. Occasionally, however, brain tumors may be the presenting tumor in such cancer-prone patients.

In addition to the familial occurrence of brain tumors as part of recognized inherited cancer syndromes, there are rare pedigrees in which several family members develop a specific histologic type of brain tumor consistent with autosomal dominant inheritance, but other signs of phakomatoses or non-CNS malignancies are absent. These pedigrees are described later under the respective tumor type.

### 124.4.1 Neurofibromatosis 1

Neurofibromatosis 1 (NF1) is transmitted in an autosomal dominant manner, with 50% of patients representing de novo mutations (reviewed in Reference (10)). The gene is located on chromosome 17q and encodes a protein with properties of a guanosine triphosphatase (GTPase) activating protein. NF1 affects approximately 1 in 3000 individuals around the world. Details about NF1 are presented in Chapter 121. Although the characteristic lesion of NF1 is the neurofibroma, a benign

TABLE 124-1

Inherited Cancer Syndromes and Tumors of the Nervous System

Syndrome	Gene	Location	Predominant Tumor Type
Neurofibromatosis 1 peripheral	NF1	17q11.2	Neurofibroma, malignant nerve sheath tumor, optic glioma
Neurofibromatosis 2 ependymoma	NF2	22q12	Schwannoma, meningioma
Von-Hippel–Lindau disease	VHL	3q25	Capillary hemangioblastoma, renal cell carcinoma, pheochromocytoma
Tuberous sclerosis astrocytoma	TSC1	9q34	Subependymal giant cell TSC2 16p13.3
Li–Fraumeni syndrome	P53	17p13.1	Soft-tissue and bone sarcomas, breast carcinoma, glioma, leukemia, PNET
Gorlin syndrome	PTCH	9p22	Basal cell carcinoma, PNET, meningioma
Ataxia–telangiectasia	ATM	11q22-23	Lymphoid tumors
Cowden syndrome	PTEN	10q23	Dysplastic gangliocytoma of the cerebellum, meningioma
Werner syndrome	WRN	8p12	Meningioma, astrocytoma
Turcot syndrome	APC	5q21	Colon carcinoma, glioblastoma
	hPMS2	7p22	PNET
	hMLH1	3p21.3-p23	

PNET, primitive neuroectodermal tumor.

tumor of the peripheral nerve, patients with NF1 may also develop gliomas (11). These lesions typically involve the optic nerves or optic chiasm and may occur in up to 15% of patients if detailed neuroimaging is used for detection. The great majority of these tumors is asymptomatic and shows little progression. The histology is typically that of a pilocytic astrocytoma. Gliomas may also occur less frequently in the brainstem and hypothalamus, and rarely in the cerebellum or spinal cord. Reports of meningiomas in NF1 most likely represent the chance association of a common brain tumor with a common genetic disorder.

### 124.4.2 Neurofibromatosis 2

Neurofibromatosis 2 (NF2) is another autosomal dominant condition, affecting approximately 1 in 40,000 individuals (12). NF2 is due to mutation in a gene on chromosome 22q that encodes a cytoskeletal protein (13,14). It is described in detail in Chapter 121. NF2 patients are characterized by bilateral vestibular schwannomas, a hallmark feature of the disease. Commonly, NF2 patients have other cranial and spinal schwannomas and meningiomas. Gliomas are also found in patients with NF2, most commonly in the spinal cord (15). Rarely, gliomas may occur in the posterior fossa or in a supratentorial location, and they may represent the sole manifestation of NF2 in the occasional patient (16). About 80% of gliomas in NF2 patients are intramedullary spinal or cauda equina tumors, and the vast majority of these are ependymomas (17,18).

### 124.4.3 Von Hippel–Lindau Disease

Von Hippel–Lindau (VHL) disease is transmitted as an autosomal dominant trait and is described in detail in Chapter 121. The responsible gene is located on chromosome 3p (19). Hemangioblastomas are found in the majority of patients with VHL disease (20) and may be a cause of death (21). The majority of hemangioblastomas in VHL disease occur in the cerebellum, followed by locations in the spinal cord and brainstem (20,21). Approximately half the tumors are asymptomatic (20). Capillary hemangioblastomas in VHL patients tend to manifest in younger patients than sporadic capillary hemangioblastomas and are more often multifocal (20).

### 124.4.4 Tuberous Sclerosis

Tuberous sclerosis (TS) is the second most frequent hereditary tumor syndrome of the nervous system after NF1 (22). Details are presented in Chapter 121. Two different genes have been linked to the onset of TS, TSC1 located at chromosome 9q34 and TSC2 located at 16p13.2 (23,24). Neuroimaging studies show CNS lesions in the great majority of patients with TS, including hamartomas such as cortical tubers and subependymal nodules (25).

Only approximately one-fourth of the lesions are tumorous and represent giant cell astrocytomas. Giant cell astrocytomas, in contrast to subependymal nodules, show marked enhancement.

### 124.4.5 Li–Fraumeni Syndrome

The Li–Fraumeni syndrome is a rare, dominantly inherited syndrome associated with germline mutations in the *TP53* gene (26). Although soft-tissue sarcomas and breast cancers predominate, approximately 13% of patients develop brain tumors that typically show the histology of astrocytic glioma, followed by PNETs (27). In addition to patients with the Li–Fraumeni syndrome, *TP53* germline mutations have been occasionally identified in patients with nonfamilial malignancies with early onset or multifocality. First-degree relatives of these patients are also at an increased risk of gliomas (28,29).

### 124.4.6 Gorlin Syndrome

Gorlin syndrome, also called nevoid basal cell carcinoma syndrome, is an autosomal dominant disorder leading to the development of multiple basal cell carcinomas of the skin as well as palmar and plantar pits, odontogenic keratocysts, and skeletal anomalies (30). Childhood medulloblastoma, meningioma, craniopharyngioma, and neurofibroma have been described in patients with Gorlin syndrome (31–33). Gorlin syndrome has been linked to mutations in the tumor suppressor gene *PTCH*, which is the human ortholog of *Drosophila* patched (34–36). Somatic mutations in *PTCH* have been detected in sporadic basal cell carcinomas, PNETs, medulloblastomas, and certain other types of sporadic tumors (37–39).

### 124.4.7 Ataxia-Telangiectasia

Ataxia-telangiectasia is a recessive trait mapped to the *ATM* gene on chromosome 11q. *ATM* is a PI3-kinase-related protein kinase whose function in cell cycle control is lost by truncating mutations that result in loss of the C-terminally located kinase domain or by point mutations (40,41). Lymphoid malignancies are frequently seen in patients with ataxia-telangiectasia. Although solid tumors occur, primary CNS tumors are infrequent (25a,42).

### 124.4.8 Cowden Syndrome

Cowden syndrome, also known as multiple hamartoma syndrome, is an autosomal dominant cancer syndrome that predisposes to a variety of hamartomas and neoplasms. The major CNS lesion associated with the disease is dysplastic gangliocytoma of the cerebellum (Lhermitte–Duclos disease) (43). Other associated CNS lesions include megalencephaly and gray matter heterotopias. Occasional cases of meningiomas in patients

with Cowden syndrome have also been documented (44). Peripheral manifestations include multiple trichilemmomas of the skin, cutaneous keratoses, oral papillomatosis, gastrointestinal polyps, hamartomas of soft tissues, thyroid tumors, and benign and malignant breast tumors (45,46). Germline mutations in the *PTEN* tumor suppressor gene at 10q23 have been linked to Cowden syndrome (47,48).

#### 124.4.9 Werner Syndrome

Werner syndrome is a recessive trait with clinical symptoms resembling premature aging. The responsible gene maps to the short arm of chromosome 8, and has been identified by positional cloning (49). In addition to premature aging, some individuals with Werner syndrome develop tumors, including CNS tumors such as meningiomas and, less frequently, astrocytomas (50–52).

#### 124.4.10 Turcot Syndrome

Turcot syndrome describes a rare heterogeneous disorder characterized by the association of colonic polyposis and malignant primary neuroepithelial tumors of the CNS. Colonic polyposis in patients with Turcot syndrome appears to be the result of mutations in genes encoding Wnt signaling pathway proteins (*APC* and *beta-catenin*). Some patients with Turcot syndrome have been shown to possess mutations in the gene for familial adenomatous polyposis coli (*APC*) (53,54). A patient with Turcot syndrome and congenital hypertrophy of the pigment epithelium, commonly seen in familial *APC*, has also been described (55). The incidence of glial tumors and medulloblastomas appears to be increased in patients with colonic polyposis (see Reference (56) and references therein). On the other hand, somatic *APC* mutations are not a major cause of brain tumors. Using RNase protection analysis Mori and associates (54) did not detect any *APC* gene mutations in 47 medulloblastomas, 8 glioblastomas, 22 astrocytomas, and 2 oligodendrogliomas. Furthermore, mutations in Wnt pathway proteins are less frequent in sporadic medulloblastomas: Huang and coworkers (57) detected mutations in the *APC* or *beta-catenin* genes in only six of 46 of such tumors.

In patients with Turcot syndrome, germline mutations have been identified in three different genes. Of 14 families with Turcot syndrome, 10 had germline mutations in the *APC* gene, and two had mutations in *hPMS2* or *hMLH1*-mismatch repair genes (45a). Mutations in *hPMS2* may predispose the patient to extreme DNA instability. One patient was studied who had an inherited *hPMS2* missense mutation. Genetic characterization of the patient's tumors, which included one astrocytoma, three colon carcinomas, and two colon adenomas, showed additional mutations in the *TGFbetaRII*, *E2F-4*, *hMSH3*, *hMSH6*, *APC*, or *TP53* genes (58).

### 124.5 RELATIVE RISK OF CANCER IN FIRST-DEGREE RELATIVES

In epidemiologic studies, only a small increased risk for brain tumors was detected for relatives of patients with brain tumors. Choi and associates (59) found a ninefold increase in the incidence of brain tumors among relatives of glioma patients compared with controls. Even this increased relative risk translated into the relatively small absolute risk of 0.6% in this study. In other studies, the increased relative risk was less significant (60,61). Gold and colleagues (62) compared several risk factors in 361 children with brain tumors to 1083 matched controls. Although a family history of tumors did not contribute to an increased risk of brain tumors in children, a modest increase in risk of childhood brain tumors was associated with a maternal family history of birth defects. Kuijten and coworkers (63) found a modestly increased risk of childhood cancers only in relatives of patients with PNETs, whereas for relatives of astrocytoma patients, this risk was not significantly increased.

### 124.6 GLIAL TUMORS

Gliomas are a heterogeneous group of mostly sporadic neoplasms derived from glial cells. They account for about 40–45% of all intracranial tumors and, thus, are the most common tumors among the primary CNS neoplasms (1). Depending on morphologic appearance and presumed histogenesis, gliomas are subdivided into several subgroups, the most important being astrocytic tumors (including the glioblastoma), oligodendroglial tumors, mixed gliomas (oligoastrocytomas), and ependymal tumors.

A genetic predisposition for the development of gliomas is seen in NF1 and NF2, Li-Fraumeni syndrome, TS, Gorlin syndrome, Turcot syndrome, and ataxia-telangiectasia. The specific type of glioma or its location may vary depending on the disorder. For example, pilocytic astrocytoma of the optic nerve is typical for NF1, whereas ependymoma of the spinal cord is characteristic for NF2. Of 282 children with astrocytoma examined by Kibirige and colleagues (64), 21 had a diagnosis of NF1 and four had TS. Familial glioma not associated with a specific genetic syndrome does occur but is infrequent, and it is exceedingly rare to see more than two first-degree relatives with glioma. Vieregge and associates (65) reviewed 39 reports of familial glioma and concluded that 60% involved affected siblings. Although gliomas are seen in familial *APC* and Turcot syndrome, somatic mutations in the *APC* gene in primary brain tumors are rare and were not detected in 91 neuroepithelial tumors including gliomas (54).

#### 124.6.1 Astrocytoma and Glioblastoma

Astrocytoma is a generic term applied to diffusely infiltrating tumors composed of well-differentiated neoplastic astrocytes (8). The astrocytomas, or astrocytic gliomas,

may be subdivided into two major groups: (1) the more common group of diffusely infiltrating tumors, comprising astrocytoma, anaplastic astrocytoma, and glioblastoma and (2) the less common group of tumors with more circumscribed growth consisting of pilocytic astrocytoma, pleomorphic xanthoastrocytoma (PXA), and subependymal giant cell astrocytoma of TS. Astrocytomas tend to infiltrate the surrounding brain. Therefore, despite their slow growth, even well-differentiated astrocytomas (corresponding to grade II histologically) tend to recur. Anaplastic (malignant) astrocytomas show diffuse anaplasia (e.g. increased cellularity, pleomorphism, nuclear atypia, and mitotic activity). Histologically, they correspond to grade III. Glioblastoma is an anaplastic, often cellular brain tumor composed of poorly differentiated, fusiform, round or pleomorphic cells and occasional multinucleated giant cells. The presence of prominent vascular proliferation or necrosis is essential for the histologic diagnosis. Histologically, glioblastomas correspond to grade IV. Astrocytomas and glioblastomas account for about 17% of primary brain tumors in adults, whereas in children they account for only 4%.

The most malignant type of glioma, the glioblastoma (WHO grade IV), is also the most common, making up close to 50% of all gliomas (66). The incidence of glioblastomas peaks between 45 and 60 years of age. In adulthood, glioblastomas share a preferential supratentorial location with the other diffuse astrocytomas. By computed tomography (CT) and magnetic resonance imaging (MRI), these tumors usually appear as a ring structure with a hypodense center (necrosis) surrounded by a ring of contrast-enhancing vital tumor tissue and edema. Macroscopically, typical glioblastomas are largely necrotic masses with a peripheral zone of fleshy gray tumor tissue. Intratumoral hemorrhage is a frequent finding. Histologically, glioblastomas are cellular tumors that may show a variety of tissue and cell differentiation patterns.

Although they are histologically indistinguishable, there are genetically distinct subtypes of primary and secondary glioblastoma. Primary glioblastomas account for the vast majority of cases in adults older than 50 years. After a short clinical history of usually fewer than 3 months, they manifest *de novo*, without clinical or histologic evidence of a less malignant precursor lesion. In contrast, secondary glioblastomas usually develop in patients younger than 45 years of age, with malignant progression from grade II or III astrocytoma. The interval of progression may be from less than 1 year to as long as 10 years, with a median interval of 4–5 years (67). The prognosis of glioblastoma patients is extremely poor, with a median postoperative survival time of only 12 months (68).

### 124.6.2 Molecular Genetics of Astrocytic Gliomas

Several molecular mechanisms have been implicated in the development of gliomas and their progression to more

malignant histologic grades on recurrence. These involve activation of dominantly acting oncogenes, as well as inactivation of recessive tumor suppressor genes. Among primary glioblastomas, 60% have overexpression of the epidermal growth factor receptor (EGFR) and 40% have EGFR amplification. EGFR VIII, a mutant EGFR receptor, is coexpressed in nearly 50% of glioblastomas with EGFR amplification (69). Other genetic alterations observed in primary glioblastomas include overexpression of the *MDM2* (murine double minute 2) gene and mutation loss of the tumor suppressor protein PTEN. Secondary glioblastomas typically have mutations of the *p53* tumor suppressor gene and overexpression of platelet-derived growth factor (PDGF) ligands and receptors (67). Genetic alterations on chromosomes 9p, 10q, 11p, 17p, 19q, and 22 have also been associated with events leading to gliomas.

As we observe these molecular genetic alterations of tumors, efforts are targeted at correlating these changes with clinical parameters including prognosis and response to treatment. As an example, we can look more closely at the *MGMT* gene located on chromosome 10q26, which encodes a DNA-repair protein that removes alkyl groups from the O6 position of guanine. High levels of *MGMT* activity diminish the therapeutic effects of alkylating agents. Loss of *MGMT* expression occurs by epigenetic silencing of the *MGMT* gene by promoter methylation. In a series of 206 glioblastomas, the *MGMT* promoter was methylated in 45%. This change correlated with a statistically significant increase in median overall survival of 18.2 months compared with 12.2 months in those without promoter methylation. Moreover, those patients with the *MGMT* promoter methylation status benefited from a combination of chemotherapy with an alkylating agent, temozolomide, and radiation, with a median survival of 21.7 months compared with treatment with radiation alone, with a median survival of 15.3 months (70).

Genetic alterations leading to glioma formation are described later in greater detail, and a simplified summary of events leading to glioma formation and progression is shown in Figure 124-1.

**124.6.2.1 Chromosome 2q and IDH1.** The isocitrate dehydrogenase 1 (*IDH1*) gene encodes for an enzyme in the citric acid cycle that converts NAD<sup>+</sup> to NADH and drives the oxidative decarboxylation of isocitrate. Genomic analysis uncovered somatic mutations in 12% of glioblastoma multiforme (GBM) tumors. Large-scale screening of gliomas showed that mutations were uncommon (5%) in primary adult GBMs, but they were present in 85% of secondary glioblastomas (71). Mutations in a functional equivalent region of *IDH2* (chromosome 15q) were also observed in low-grade gliomas, but at 1/20 the frequency (71). Pediatric gliomas, as well as primary adult GBMs, rarely contain mutations in *IDH1* (27,71–73). *IDH1* mutations are an early transformation event that occurs in tumors that acquire either *p53* mutations or 1p and 19q deletions (72,74). Tumors with *IDH1* mutations appear to occur in a genetically distinct

subtype given their common occurrence in secondary GBMs, and mutual exclusivity with other common genetic aberrations including PTEN deletions and EGFR copy-number amplification (16).

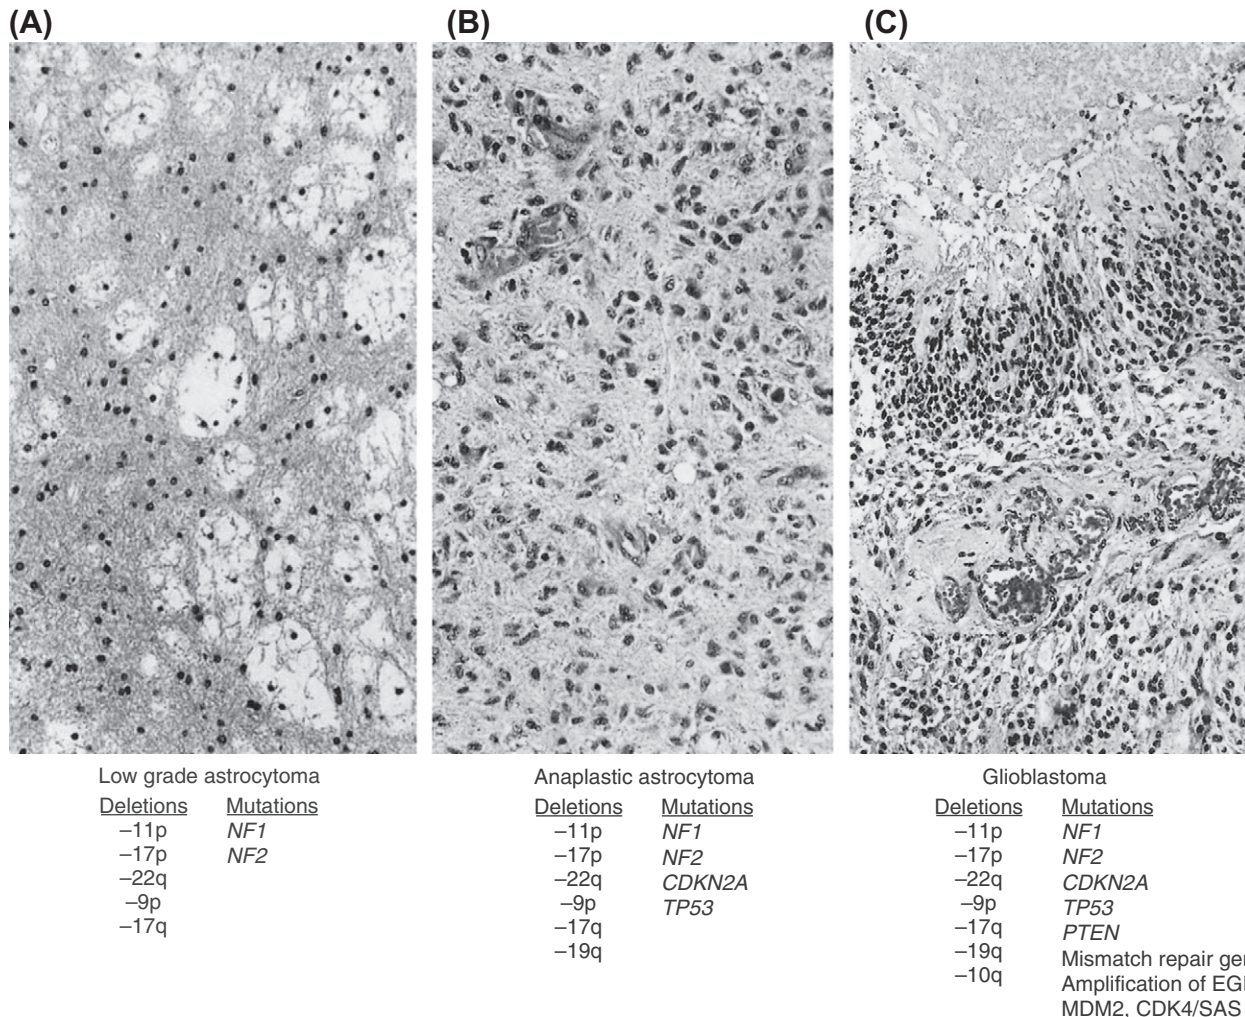

**124.6.2.2 Chromosome 4q and PDGFR $\alpha$ .** Activation of platelet-derived growth factor receptor alpha (PDGFR $\alpha$ ) initiates mitogenic signaling and is amplified in up to 17% of GBMs and is observed in all four subtypes, but alterations are more common in the proneural subtype (16,34).

**124.6.2.3 Chromosome 7p and EGFR.** Amplification of chromosome 7 is the most common alteration observed in glioblastomas, resulting in gains of EGFR copy number. EGFR amplifications are observed in 50–60% of GBM tumors and are correlated with increased expression. Although EGFR activation typically results from ligand stimulation, a common mutation in a quarter to two-thirds of GBM tumors with EGFR amplifications express an aberrantly active version

referred to as EGFRvIII. EGFRvIII is constitutively active, avoids degradation, and contributes to genomic instability (75). Alternatively, the majority of tumors that lack EGFR amplifications have little or no detectable levels of EGFR (60). Alterations in EGFR are observed in all four tumor subtypes, but are a hallmark of the classic subtype, with a mutually exclusive relationship between EGFR and TP53 mutations (7,16,68).

Cyclin dependent kinase 6 (CDK6) contributes to the progression through the G1 mitotic phase and is commonly upregulated in gliomas (76,77). Although chromosome 7 has common regions of amplification in gliomas, the 7q21 region containing CDK6 is not coamplified with MET or EGFR, suggesting a distinct selective pressure (3). Amplifications in the CDK4 gene occur in 18% of glioblastoma tumors (78), and tumors lacking CDK4 alterations are likely to contain mutations in RB1 (59).

The MET proto-oncogene, also referred to as c-MET, encodes for the hepatocyte growth factor receptor (HGFR)

**FIGURE 124-1** Simplified schematic representation of glioma pathogenesis and progression. (A) Fibrillary astrocytoma with low cellularity and microcyst formation; (B) anaplastic astrocytoma with nuclear atypia, and frequent mitoses; (C) glioblastoma with small, anaplastic tumor cells, vascular proliferation, and necrotic areas with pseudopalisading of tumor cells. Mut., mutation, amplif., amplification. Parentheses indicate a minor or less well-established role of a particular genetic change in the pathogenesis of gliomas. (From Kleihues, P.; Burger, P. C.; Scheithauer, B. W. *Histological Typing of Tumours of the Central Nervous System, 2nd ed.*; Springer-Verlag, Heidelberg, 1993.)

protein. The expression of MET correlates with tumor grade (79), and gene amplification appears to occur independent of the EGFR region (80). MET amplifications in gliomas are far less common than those of EGFR, but are a part of the upstream PI3K pathway (78). Inhibition of MET by antibodies reduces tumor growth in vivo (80), and higher expression is associated with a shorter time to tumor recurrence (79). MET signaling contributes to drug resistance (81), and synergistically regulates EGFR signaling, particularly with EGFRvIII (82–84). MET itself is regulated by the tumor suppressor PTEN (83,85). Interestingly, MET may be critical to cancer stem cells, since expression induces signaling network alterations producing a cancer stem cell-like phenotype (6).

**124.6.2.4 Chromosome 9p.** The critical gene on chromosome 9 is the *CDKN2A* (MTS1) tumor suppressor gene, which encodes p16 (p16INK4a), a negative regulator of cell cycle progression (86). *CDKN2A* mutations have been identified in melanoma, astrocytoma, and glioblastoma (87,88). The p16 protein normally binds the cyclin D-cyclin-dependent kinase 4 or 6 (Cdk4, Cdk6) complex, thereby inactivating the retinoblastoma protein Rb, resulting in cell cycle arrest (89).

Glioblastomas frequently show deletions of one or both copies of the *CDKN2A* tumor suppressor gene on 9p21. Schmidt and coworkers (90) found homozygous deletion of *CDKN2A* in 41% and hemizygous loss of *CDKN2A* in 28% of primary glioblastomas. In glioblastoma cell lines, the incidence of homozygous *CDKN2A* loss seems to be even higher, reaching 70% (42a). In addition, inactivation of *CDKN2A* either by point mutation or by 5' CpG island methylation has been found in some glioblastomas (83,91). Chromosome 9p deletions are not exclusive to malignant astrocytomas, and may occur in lower grade astrocytomas and oligodendrogliomas (92). Interestingly, there is a well-established mutually exclusive relationship between mutations in *CDKN2A* and *RB1*, whereas cells that lack mutations in *CDKN2A* typically have mutations in *RB1* (59,93). Molecular subtype analysis of tumors reveals that although deletion events in the *CDKN2A* gene are common (70%), they occur in 95% of tumors with the classic subtype (16a).

**124.6.2.5 Chromosome 10.** Monosomy 10 is a frequently detected karyotypic abnormality in gliomas and is typically associated with a more malignant histologic type. Using comparative genomic hybridization, Schrock and colleagues (94) demonstrated chromosome 10 loss in one of two astrocytomas and seven of seven glioblastomas. The incidence of chromosome 10 loss in glioblastomas varies between different studies, ranging from 60% to more than 90% of the cases (82). Loss of heterozygosity (LOH) in gliomas for chromosome 10 genetic markers often involves markers spanning the whole chromosome; however, partial deletions have recently been identified (95).

Three different regions on both arms of chromosome 10 have been implicated as potential sites of

glioblastoma-associated tumor suppressor genes (95). The region most frequently deleted is located at distal 10q and spans approximately 5 cM between the loci D10S587 and D10S216 (96). A candidate tumor suppressor gene designated *DMBT1* ("deleted in malignant brain tumors 1"), has been cloned and mapped to this region (97). Intragenic homozygous deletions in *DMBT1* were found in about 23% of glioblastomas (97). Another candidate gene from distal 10q is the *MXI1* gene, which codes for a negative regulator of the Myc oncoprotein. Mutations of *MXI1* have been detected in prostate cancer (98). Glioblastomas have not been studied in detail for *MXI1* mutations. In contrast, somatic mutations in the *PTEN* tumor suppressor gene at 10q23 have been detected in about one-third of glioblastomas (74,99,100). *PTEN* is also altered in some breast carcinomas, prostate carcinomas, and malignant melanomas (99,100).

Deletions in chromosome 10, including the region containing the tumor suppression gene *PTEN*, commonly occur in tumors containing *EGFR* amplifications (101,102). These results suggest that *PTEN* function may serve to modulate the effects of enhanced *EGFR* signaling in gliomas and has been implicated as a means for resistance to *EGFR* inhibitor therapy (98). Mutations are observed in 23% of GBM tumors, but deletions in the gene region are far more common and occur in 85% of tumors, although less frequent in the proneural subtype (16a). The 10q22–23 region that is often deleted also contains a novel tumor suppressor gene annexin 7 (*ANXA7*). Deletions in *ANXA7* occur in 77% of tumors and mutations are observed in 6%, resulting in lower *EGFR* degradation and a worse survival outcome (101).

**124.6.2.6 Chromosome 11p.** Eleven of 43 malignant astrocytomas showed LOH of markers in 11p (103). The *HRAS* gene that maps to this region was excluded as a candidate gene by single strand conformation polymorphism (SSCP) analysis. Loss is detected in low- as well as high-grade gliomas, suggesting that these events occur early in tumorigenesis.

**124.6.2.7 Chromosome 12.** Cyclin dependent kinase 4 (*CDK4*) facilitates cell cycle progression by regulating *RB1*. Amplifications of *CDK4*, like *CDK6*, are observed in glioblastomas and are often overexpressed (77,104). Activation of retinoblastoma signaling is predictive of the effects of *CDK4* inhibition (76), while tumors with wild-type *CDK4* are more likely to contain *RB1* mutations (59).

MDM2 is a negative regulator of tumor suppressor p53, preventing its transcriptional activity and targeting it for proteosomal degradation. Amplification of MDM2 occurs in 14% of glioblastomas (78) and is associated with worse survival (104).

**124.6.2.8 Chromosome 13 and *RB1*.** The retinoblastoma protein (*RB1*) is a critical tumor suppressor gene that blocks cell cycle progression by inhibiting E2F transcription factors when unphosphorylated. On phosphorylation by cyclin-dependent kinases, *RB1* is targeted for degradation and the E2F transcription factors

are allowed to be active. The RB signaling network is often disrupted in GBMs (50,69). Mutations in RB1 are observed in glioblastomas, particularly when tumors are wild type of cyclin dependent kinases (59,76,93). Chromosomal deletions in the region that correspond to the *RB* gene are a frequent occurrence in GBMs (44%), but are less common in the classic subtype (16a).

**124.6.2.9 Chromosome 14q and NFKBIA.** NF- $\kappa$ B signaling contributes to invasiveness and drug resistance. NFKBIA inhibits the nuclear factor of kappa light polypeptide gene enhancer in B cells (NF- $\kappa$ B) transcription factor by sequestering the transcription factor dimer in the cytoplasm. Following stimulation, NFKBIA is phosphorylated and targeted for proteosomal degradation, allowing NF- $\kappa$ B to translocate to the nucleus and transcribe target genes. Constitutive activation of NF- $\kappa$ B is commonly observed in GBMs and can be achieved through multiple signaling pathways. Monoallelic deletions in the chromosome 14q region corresponding to the *NFKBIA* gene are observed in approximately a quarter of GBM tumors (23,92). Deletions of NFKBIA allow for NF- $\kappa$ B signaling in tumors lacking EGFR amplification and are not typically observed in tumors with a classic phenotype (92).

**124.6.2.10 Chromosome 17 TP53 and NF1.** Loss of chromosome 17p is an early and frequent event in astrocytomas, and losses are frequently accompanied by mutation in the *TP53* gene, which is located in 17p13.1. This was not surprising because the occurrence of glial tumors in patients with the Li-Fraumeni syndrome pointed to the importance of the *TP53* gene in the formation of sporadic gliomas. In addition, Kyritsis and coworkers (28) identified *TP53* germline mutations in six of 19 patients with multifocal glioma, including two with a family history of cancer, one with another primary malignancy, and two with all three risk factors; one of four patients with unifocal glioma, another with primary malignancy, and a family history of cancer; and two of 15 patients with unifocal glioma and a family history of cancer but no second malignancy. In a family ascertained through the occurrence of childhood adrenocortical carcinoma a mutation of codon 307 in exon 8 was identified in the proband's tumor as well as in an astrocytoma from the proband's father (29). However, van Meyel and coworkers (105) did not identify germline mutations in 26 members of 16 families with glioma in exons 5 through 9 of the *TP53* gene.

The wild-type *TP53* gene product is a nuclear phosphoprotein that suppresses cell and tumor growth. In a study of 120 primary brain tumors, *TP53* mutations were detected only in 59 astrocytic tumors (106). Of these, six tumors with *TP53* mutations were either anaplastic astrocytomas or glioblastomas. Four of the six tumors had lost heterozygosity for 17p markers as well. Del Arco et al. (84) suggested a two-step model for the inactivation of the *TP53* gene in astrocytomas. A single *TP53* mutation seemed to occur in the initial stage of tumorigenesis,

because low-grade astrocytomas were heterozygous for the mutation; loss of the remaining wild-type allele was associated with a higher degree of malignancy. Sidransky et al. (107) proposed that histologic progression of astrocytomas was associated with a clonal expansion of cells that had previously acquired a mutation in the *TP53* gene. By studying low-grade tumors that had recurred as more malignant tumors they could show that a subpopulation of cells in the initial tumor that contained *TP53* mutations made up the majority of cells in the recurrent tumor, which had progressed to glioblastoma. Inactivation of *TP53* may not be an obligatory step because four of 13 glioma cell lines contained a nonmutated *TP53* gene with wild-type function in a functional assay using transcriptional elements that are induced by wild-type but not mutant *TP53* (108). However, these tumors may contain amplifications of the *MDM2* gene (see later).

Wild-type p53 has a short half-life, and is present in such small quantities in normal cells that it cannot be detected immunocytochemically. Mutations in the *TP53* gene are associated with a slower turnover and may result in abnormal expression leading to p53 accumulation in the cell nucleus so that staining can be detected by immunocytochemistry. Aberrant or increased expression of p53 has been observed in many astrocytic tumors (109). Haapasalo et al. (110) stained sections of 102 astrocytic tumors with two antibodies to wild-type and mutant *TP53*. None of the grade 1 astrocytomas were positive, but 29% of grade 2 tumors and 49% of grade 3–4 astrocytomas were positive. Some mutations in the conserved *TP53* exons may be missed by immunocytochemistry, and p53 accumulation may occur independent of mutations in these exons (111). Nonetheless, mutations in p53 are well established in GBMs, particularly those without EGFR amplifications and from a proneural subtype (7,16a,68).

The *NF1* gene encodes for the tumor suppressor protein neurofibromin 1 on chromosomal region 17q11.2 that negatively regulated the oncogenic Ras pathway. Although mutations in this gene are commonly associated with neurofibromas, mutations are found in 17% of GBMs. In fact, 53% of GBMs with the mesenchymal phenotype either contain deletions in the *NF1* gene or harbor sequence mutations (16a).

**124.6.2.11 Chromosome 19.** LOH on chromosome 19p is a common alteration found in astrocytomas (112,113). Ritland et al. (112) showed LOH at 19p13.2-pter in 17 of 23 studied astrocytomas, consistent with findings of the previous work by von Deimling et al. (113). Alterations on chromosome 19q are also less commonly linked to the development of astrocytomas, involving 19q13.2–q13.4 (114).

**124.6.2.12 Chromosome 22.** Using comparative genomic hybridization, Schrock et al. (21) identified loss and gain of chromosome 22 in malignant gliomas. Five of nine tumors had lost all or part of chromosome 22q. A novel amplification site was mapped to chromosome 22q12.

**124.6.2.13 Gene Amplifications.** The most commonly amplified gene in glioblastomas is the gene coding for the *EGFR* on chromosome 7, correlating with the frequent observation of trisomy 7 in glioblastomas. *EGFR* is a transmembrane protein with tyrosine kinase activity. Its extracellular domain binds EGF and transforming growth factor (TGF)- $\alpha$ . *EGFR* may interact with its ligands in an autocrine fashion, leading to an increase in cell proliferation.

*EGFR* abnormalities are specifically associated with GBM (115), and *EGFR* amplification is associated with a shorter median survival (116). In a study of 58 glioblastomas, von Deimling et al. (113) detected *EGFR* gene amplification only in tumors with loss of chromosome 10, suggesting that *EGFR* abnormalities follow chromosome 10 loss in the cascade of tumor progression.

Abnormalities of the *EGFR* gene in glioblastomas include most commonly not only amplification and overexpression but also rearrangements and deletions resulting in abnormal binding of ligands (104,115,117). Most frequently, rearrangements are deletions affecting the 5' end (coding for the extracellular domain) and, more rarely, the 3' end (coding for the intracellular domain) (81). The most common of these rearrangements, an in-frame deletion of 801bp resulting in the aberrant splicing of exon 1 to exon 8, causes the expression of a truncated receptor molecule lacking parts of the extracellular domain necessary for ligand binding. Functional characterization of this *EGFR* variant has revealed that it shows constitutive tyrosine kinase activity and may thereby confer enhanced tumorigenicity on human glioma cells (84).

In addition to *EGFR*, the cellular *MDM2* (murine double minute 2) gene on 12q is amplified in a large percentage of human sarcomas and in other human tumors. The gene product can complex with p53 and inhibit its function (118). Reifenger et al. (119) studied 157 primary brain tumors and found that the *MDM2* gene is amplified and overexpressed in 8–10% of anaplastic astrocytomas and glioblastomas. No *TP53* mutations or LOH for 17p were detected in these tumors, suggesting that *MDM2* amplification may be an alternative mechanism for abnormally regulated p53 growth control. Reifenger et al. (120) showed that 15% of astrocytomas and glioblastomas show amplification of 12q13–14 and identified some tumors that had amplicons not containing *MDM2*, but *CDK4* and *SAS*. More recently, another murine double minute gene, *MDM4*, has been shown to be amplified in gliomas lacking *TP53* mutations that lacked *MDM2* amplification (121). Other genes including *NMYC* and *MET* may be amplified as well, albeit at a much smaller frequency (72,122).

Pilocytic astrocytomas constitute a separate clinical and histopathologic entity, and are the most common astrocytic tumors in children. In contrast to adult astrocytomas, allelic losses on chromosomes 10, 17p, and 19q are not found in pilocytic astrocytomas, nor

are alterations in the *EGFR* gene. von Deimling et al. (123) detected loss of alleles on 17q in 4 of 20 tumors. One tumor contained an interstitial deletion encompassing the region of the *NF1* gene. Mutations of the *TP53* gene were not identified in 12 juvenile pilocytic astrocytomas (124).

### 124.6.3 Oligodendroglioma

Oligodendroglioma is a tumor composed predominantly of neoplastic oligodendrocytes (8). Oligodendrogliomas are typically slow growing and usually occur during adulthood. They are most commonly located in the cerebral white matter and deep gray structures. Oligodendrogliomas have a lesser tendency to malignant transformation than astrocytomas. Histologically, oligodendrogliomas most often correspond to WHO grade II, whereas the anaplastic oligodendrogliomas are WHO grade III.

Most oligodendrogliomas are sporadic neoplasms. Occasional cases of familial clustering have been reported by Parkinson and Hall (125) (oligodendroglioma in two brothers), Roosen et al. (126) (oligodendroglioma in a mother and her daughter), Roelvink et al. (127) (oligodendroglioma in twin sisters), and Ferraresi et al. (128) (oligodendroglioma in a father and his son). In addition, a family with polymorphous oligodendrogliomas in brother and sister has been shown, whose tumors were immunoreactive for p53, suggesting that each tumor was associated with a mutation in the *TP53* gene (129).

### 124.6.4 Molecular Genetics of Oligodendrogliomas

There are multiple molecular mechanisms that account for the development of oligodendrogliomas. Genetic alterations on chromosomes 1, 10, and 19 have been associated with events leading to oligodendrogliomas. Amplification of *EGFR* has also been observed in oligodendrogliomas. *EGFR* amplification is considerably more infrequent than in other glial tumor types, whereas *EGFR* overexpression is common. LOH on the chromosome arms 1p and 19q is frequent in oligodendrogliomas. LOH of chromosome 1p or combined loss involving chromosomes 1p and 19q is statistically significantly associated with both chemosensitivity and longer recurrence-free survival after chemotherapy (76). LOH on 1p and 19q in patients with anaplastic oligodendrogliomas treated with chemotherapy with or without radiation had a median time to progression of 86 months and a median overall survival of 91 months compared with those without LOH who had a median time to progression of 39 months and a median overall survival of 46 months (130).

**124.6.4.1 Chromosome 1.** Loss of alleles on the short arm of chromosome 1 is common in oligodendroglioma neoplasms. Reifenger et al. (120) showed LOH on

1p in 67% (14/21) of studied tumors. Bello et al. (101) found LOH on 1p in six of six oligodendrogliomas and five of six anaplastic oligodendrogliomas. Kraus et al. (131) detected LOH in three of nine oligodendrogliomas and three of six anaplastic oligodendrogliomas.

In anaplastic oligodendrogliomas, when chromosome 1p deletions are absent, chromosome 9p deletions often occur, and loss of *CDKN2A*, which encodes a cell cycle regulatory molecule (p16INK4A). *CDKN2A* has a close homolog, *CDKN2C*, located at chromosome 1p32. Tipped by these reciprocal 1p/9p deletions, Pohl et al. (132) demonstrated homozygous deletions of the *CDKN2C* gene on the short arm of chromosome 1 in a subset of oligodendrogliomas, suggesting that *CDKN2C* may be oncogenic in these tumors.

Concurrent deletions of chromosome regions 1p and 19q are commonly observed in oligodendrogliomas and may be an early transformation event (32), although somatic alterations in these regions are rarely observed (33). Patients with tumors containing these deletions have better survival outcomes and response to treatment (133,134). Deletions of 1p and 19q in pediatric oligodendrogliomas are rare (12). Interestingly, there is a high frequency of concurrence with 1p and 19q LOH and mutations in *IDH1* in oligodendrogliomas (71,74), but typically do not occur in tumors with p53 alterations (130).

**124.6.4.2 Chromosome 2q and *IDH1*.** Mutations in the isocitrate dehydrogenase 1 (*IDH1*) gene are common in oligodendroglial and oligoastrocytic tumors (27,71,73,74). Mutations in *IDH1* occur at amino acid R132 in 80% and 86% of grade 2 oligodendrogliomas and grade 3 anaplastic oligodendrogliomas, respectively (71). *IDH2*, located on 15q26, encodes for a functionally equivalent enzyme that can also be mutated in the analogous R172 residue in tumors, albeit at 1/10 to 1/20 the frequency (71). Pediatric oligodendroglial tumors and glioblastomas with oligodendroglial differentiation do not contain *IDH1* mutations (27).

**124.6.4.3 Chromosome 10.** Wu et al. (117) report a patient presenting with an oligodendroglioma that recurred with the histology of a glioblastoma 5 months later. DNA analysis of the initial tumor showed loss of alleles on chromosome 10, which is typically found in more malignant gliomas. The authors suggested that loss of chromosome 10 alleles may be predictive of malignant tumor growth even when morphologic criteria of aggressive growth are absent. Chromosome 10 deletions in low-grade oligodendrogliomas were more recently narrowed to 10q25–26 (135).

**124.6.4.4 Chromosome 19.** The most frequent genetic alteration in oligodendrogliomas is LOH on the long arm of chromosome 19 (113,114,136,137). Ritland et al. (112) examined region-specific LOH and its relation to the morphologic type of glioma. In astrocytomas, allelic loss was most commonly observed for 19p, whereas loss of alleles in 19q and retention of alleles in

19p were associated with oligodendrogliomas and mixed oligoastrocytomas (112).

Allelic loss on 19q showed a striking association with LOH on 1p, a finding suggesting a synergistic effect of both alterations in providing a selective growth advantage (78,120,131,138).

**124.6.4.5 Amplification of *EGFR*.** *EGFR* gene amplifications are the most common amplifications found in glioblastomas. *EGFR* amplifications are relatively uncommon in oligodendrogliomas, whereas overexpression of *EGFR* protein is a common feature of oligodendrogliomas. Reifenberger et al. (139) studied 13 grade II oligodendrogliomas and 20 grade III anaplastic oligodendrogliomas for *EGFR* gene amplification. They observed *EGFR* gene amplification in only one anaplastic tumor. However Reifenberger et al. (139) also observed that overexpression of *EGFR* mRNA is relatively common in both low- and high-grade oligodendrogliomas (six of 13 oligodendrogliomas, and 10 of 18 anaplastic oligodendrogliomas).

## 124.6.5 Ependymoma

Ependymoma is a tumor composed predominantly of neoplastic ependymal cells. Ependymomas are moderately cellular with low mitotic activity. They are thought to arise from the ependymal or subependymal cells surrounding the ventricles, the central canal, or within the filum terminale. Ependymomas usually present as a posterior fossa mass in children between the ages of 2 and 10 years but are also found in the spinal canal.

Ependymomas may occur in patients with NF2 and have been described in one individual who was part of a sibship with autosomal dominant meningiomas (140). Familial ependymoma occurred in a family of 11 siblings (141). Four siblings developed ependymomas or subependymomas, and one additional sibling had a brain tumor with unverified histology. Gilchrist and Savard (142) described ependymomas in two sisters and their maternal male cousin.

Because ependymomas are found in patients with NF2, the *NF2* gene was a likely candidate for an ependymoma gene; however, loss of chromosome 22 in sporadic ependymomas is rarely determined by cytogenetic or molecular studies (143–145). Rubio et al. (144) detected the loss of chromosome 22 alleles and mutation in the *NF2* gene in only one of eight ependymomas. Segregation analysis with chromosome 22 markers identified chromosome 22pter–22q11.2 as a region containing the ependymoma locus, and it clearly excluded the *NF2* gene locus (146). This is consistent with the finding in a single patient of an ependymoma-associated constitutional translocation, t(1;22) (p22;q11.2) (147). It should be noted that ependymomas in NF2 patients usually occur in the spine, whereas most sporadic tumors have an intracranial location.

Mutations in the *TP53* gene are also rare in ependymomas. In 15 ependymomas, only one contained a

silent mutation in exon 6. Metzger et al. (148) detected a germline mutation in codon 242 of the *TP53* gene in a patient with a malignant ependymoma of the posterior fossa. Several of the relatives had died at a young age from a variety of cancers. Similarly, in a survey of relatives of 195 children younger than 15 years of age with soft-tissue sarcomas, only one sib died from an ependymoma (149).

Evidence for other ependymoma loci has come from several different approaches. In addition to chromosome 22 abnormalities, cytogenetic analyses of ependymomas have shown abnormalities of chromosomes 6, 11, 16, and 17 (150–152). Comparative genomic hybridization studies and cytogenetic analysis have shown that loss of chromosome 6p is common in the pediatric ependymoma, in addition to 17p and 22q abnormalities (153,154). By immunocytochemical investigation of ependymomas using antibodies directed against schwannomin, Huynh and colleagues (155) divided ependymomas into two groups: one group with lack of staining suggesting that loss or mutation of both *NF2* alleles had occurred, and a second group with normal staining suggesting that mutation in other genes caused ependymoma formation

(Figure 124-2). An ependymoma locus in addition to *NF2* was also suggested by genetic linkage analysis of a family with autosomal dominant meningiomas and ependymomas (149).

### 124.6.6 Molecular Predictors of Glioma Progression

In gliomas, more than in any other type of brain tumor, recurrence is associated with a more malignant histologic type, and response to treatment may vary greatly despite identical histologic classification (Figure 124-3). Patients with *EGFR* gene amplification in their gliomas were found to have a significantly shorter survival than those without amplification ( $P < 0.01$ ) (116). Analysis of tumor cells in a plaque assay allowed Sidransky et al. (107) to detect a subpopulation of tumor cells that contained mutations in the *TP53* gene. Progression to a more malignant histology in the recurring tumor was due to clonal expansion of those cells containing *TP53* mutations. In a long-term follow-up study of 52 patients with low-grade astrocytomas, a trend toward more aggressive growth was detected for patients with p53-positive

**FIGURE 124-2** Detection of schwannomin in normal human vestibular nerve and ependymomas. (A) Staining of a paraffinized section of normal human vestibular nerve with an antibody raised against schwannomin (155). White and black arrows indicate cytoplasm of a vestibular neuron (N) and a satellite cell (Sa), respectively. Schwannomin is present in the cytoplasm of both vestibular neurons and satellite cells. (B) Staining of the adjacent section with the same antibody after preabsorption. (C) Detection of schwannomin in an ependymoma. In this ependymoma, endothelial cells (E, at arrow) and tumor ependymal cells were stained. (D) Absence of schwannomin in another ependymoma, as indicated by negative antibody staining in tumor cell cytoplasm (note nuclear counterstain). Cell nuclei in all sections were counterstained with aqueous hematoxylin (132 $\times$ ).

tumors (19). Five years after diagnosis, the survival estimate with the Kaplan-Meier method was 21% for p53-positive patients but 46% for patients whose tumors lacked p53 immunoreactivity. Glioblastomas in patients with Turcot syndrome caused by mutations in mismatch repair genes may have a prolonged survival (45a).

The WHO classification defines PNETs as small cell malignant tumors of childhood with predominant location in the cerebellum and a noted capacity for divergent differentiation, including neuronal, astrocytic,

Genetic disorders associated with medulloblastoma include Gorlin syndrome (31,33,34), familial APC and Turcot syndrome (45a). One patient in a family with

VHL disease presented with a PNET with multipotent differentiation in the cerebellum (102).

Familial medulloblastoma is very rare, but it has been reported in two newborn sisters and identical twin girls (157). Another sib pair was recently reported by Hung et al. (158) including a review of the relevant literature. One study detected a germline *TP53* mutation in two siblings with cerebral PNETs (159).

### 124.7.1 Molecular Genetics of Primitive Neuroectodermal Tumors

Molecular abnormalities on chromosome 9, 11, and 17 have been linked to the development of PNETs. Other common genetic abnormalities in medulloblastomas are gains of portions of chromosome 1 and deletions of 1q, 6q, 11p, and 16q (5,129,134). Mutations in the genes encoding Wnt signaling pathway proteins APC and beta-catenin occur rarely in sporadic medulloblastomas (57,160). No mutations in the *APC* gene were detected in 91 neuroepithelial tumors including medulloblastomas (54); however, 12% of sporadic medulloblastomas (of 86 tumors plus 11 cell lines investigated) had *Axin1* gene deletions (83a). The *Axin1* gene is located at 16p13.3, and its gene product Axin is a negative regulator of Wnt signaling.

**124.7.1.1 Chromosome 9.** LOH of chromosome 9q involving the Gorlin syndrome gene locus at 9q22 (*PTCH*) has been found in a subset of medulloblastomas, including desmoplastic variants (161,162). In addition, somatic mutations in the *PTCH* gene have been found in about 10–15% of medulloblastomas (37,163).

**124.7.1.2 Chromosome 11.** Three of 11 PNETs showed LOH of markers in 11p (103). The *c-HRAS* gene that maps to this region was excluded as a candidate gene by SSCP analysis.

**124.7.1.3 Chromosome 17 and *TP53*.** Isochromosome 17q has been consistently observed in cytogenetic studies of PNETs, which has been detected in about 30–50% of the tumors (133,134). Isochromosome 17q results in the loss of one copy of 17p, and molecular studies have indeed confirmed LOH on 17p in a similar percentage of medulloblastomas (80,143,164). Loss of 17p in medulloblastomas is usually not associated with *TP53* mutation (71,80,81,165–167). Mutations in the *TP53* gene are relatively infrequent in medulloblastomas. Although four of 22 tumors had lost 17p, only two harbored mutations in the *TP53* gene, and the mutation was homozygous in only one of these tumors (16a). Intense overexpression of p53 by immunocytochemical analysis of tumor sections was associated with a significantly reduced survival (168). The infrequent mutation of *TP53*, together with the finding of LOH at distal 17p not including the *TP53* locus, suggest the existence of a second, not yet identified, tumor suppressor gene located at 17p13.3 (71,169). The *HIC-1* gene is a good candidate for this suspected tumor suppressor gene (170,171),

but further studies are needed to substantiate the role of this gene in PNETs.

### 124.8 SCHWANNOMA (NEURILEMMOMA, NEURINOMA)

Schwannomas are encapsulated and sometimes cystic tumors composed of spindle-shaped neoplastic Schwann cells (8). Tumors contain cellular areas with compact elongated cells, often with palisading (Antoni A areas) and less dense areas with cells containing lipid (Antoni B).

Schwannomas account for 8% of intracranial tumors and 29% of intraspinal tumors. Vestibular schwannomas (VSs) are also (somewhat erroneously) referred to as acoustic schwannomas or neuromas and occur commonly as single tumors on the vestibular branch of the eighth cranial nerve. They have an incidence of around 13 million per year (172). In patients with NF2, vestibular schwannomas are often bilateral and occur at a much earlier age than in patients with sporadic unilateral tumors. About 4% of vestibular schwannomas are bilateral, and virtually all these patients have NF2. Schwannomas also occur on other cranial and spinal nerves. When MRI imaging is used, spinal schwannomas are as common in NF2 as vestibular schwannomas (15,18). A proband presenting with multiple spinal schwannomas harboring a deletion in the *NF2* gene has been described (173). Two relatives carrying the same deletion were subsequently shown to have asymptomatic bilateral vestibular schwannomas. A second pedigree with autosomal dominant spinal tumors, but lacking vestibular schwannomas or other CNS tumors by autopsy or MRI, has also been described (174).

Frequent loss of alleles in 22q12 in sporadic vestibular schwannomas and NF2 tumors indicated a common pathogenetic mechanism for these tumors (175). These findings were further supported by establishing linkage of NF2 to genetic markers on chromosome 22 (176), leading to the subsequent cloning of the *NF2* gene in 1993 (13,14). The *NF2* gene product, designated schwannomin or merlin (see Reference (46)), is a 595 amino acid protein of the protein 4.1 superfamily of proteins, with highest similarity to the ERM protein family (including ezrin, radixin, and moesin), which links the cell membrane and the cytoskeleton.

The action of the *NF2* gene is that of a classic tumor suppressor. Inactivation or loss of the second allele and lack of the *NF2* gene product could be demonstrated in most schwannomas ((177), see later). Reduction of schwannomin synthesis in Schwann cells by use of anti-sense oligonucleotides leads to morphologic changes and loss of cell attachment (155). Schwannomin is known to directly interact with a variety of proteins including ezrin, moesin, radixin, betaII-spectrin, actin, HRS, eIF3c, CD44, paxillin, N-WASP, magacin, PIKE-L, and EBP50/NHE-RF (39,178–186).

In addition, schwannomin colocalizes and forms complexes that may or may not be direct with betaI-integrin (21a), and CD44 (152a).

The majority of *NF2* gene mutations identified in vestibular schwannomas are deletions leading to a premature stop codon (119,156,177,187–191). Although no clear hot spots for mutations have been identified, C to T transitions leading to change of an arginine codon to a stop codon occur more commonly than expected (192). With the exception of an increased frequency of C to T transitions (192) and mutations resulting in skipping of exon 4 (193), recurrent mutations are rare in the germline or in schwannomas (194).

Most *NF2* mutations are expected to result in loss of the majority of interactions between schwannomin and other proteins. *NF2* mutation also significantly decreases schwannomin stability. Sainz et al. (177) demonstrated absence of schwannomin staining in all of 30 immunohistochemically stained vestibular schwannomas. Two other studies demonstrated loss of schwannomin expression in 93% of stained schwannomas, 75% of meningiomas, and 33% of ependymomas (155,195). Thus, in contrast to meningiomas and ependymomas, mutations in the *NF2* gene appear to be the major if not exclusive molecular event leading to schwannoma formation.

Schwannomatosis describes a condition of multiple schwannomas and represents a unique class of NF that may or may not involve *NF2* gene mutations (196). Patients with schwannomatosis lack vestibular schwannomas, and some cases show multiple schwannomas localized to just the spine. Some patients with schwannomatosis have been characterized to possess no identifiable *NF2* gene mutations (75). In another study, pedigree analysis of 20 families with spinal schwannomatosis revealed truncating *NF2* gene mutations and LOH (197). Some patients proved to be sporadic mosaics for *NF2* gene mutations, whereas others had familial. This is reviewed in the phakomatosis chapter (21); schwannomatosis is associated with SMARCB1 mutations in the germline, and homozygous loss of SMARCB1 and *NF2* in tumors.

## 124.9 MENINGIOMA

Meningioma is a tumor composed of neoplastic meningeothelial (arachnoid) cells (8). Several histologic variants are recognized, such as meningothelial, fibrous (fibroblastic), transitional, and psammomatous meningioma.

Meningiomas are the most common benign brain tumors, and account for about 15% of all intracranial tumors and 25% of intraspinal tumors. The frequency of meningioma increases with advancing age, and meningiomas are more common in women. Although meningiomas are frequently attached to the dural membranes, they may occur in unusual sites, for example, within the ventricular space.

Meningiomas occur frequently in patients with *NF2* (12,177,198), and less frequently in Werner and Gorlin syndromes. Many reports of familial meningioma may represent patients with *NF2* who were inadequately evaluated for the presence of small vestibular or spinal schwannomas or lens opacities. For example, Delleman et al. (85) reported a family with four members in two generations with meningiomas. Other signs of *NF2* were missing. A fifth member of the pedigree, however, had multiple meningiomas and vestibular schwannomas. Because it is advisable to remove vestibular schwannomas before they lead to loss of hearing, signs of *NF2* should be carefully sought in all cases of familial meningioma, multiple meningiomas, or meningiomas in young patients. Dominantly inherited meningioma without other evidence of *NF2*, however, does occur (see References (73) and (199) and references therein).

### 124.9.1 Molecular Genetics of Meningiomas

**124.9.1.1 Chromosome 22.** Zang and Singer (49) reported the loss of chromosome 22 in short-term cultures of fresh meningiomas. Subsequently, Seizinger et al. (175) reported LOH of chromosome 22 DNA markers in 17 of 40 meningiomas. Molecular studies of sporadic meningiomas and meningiomas from *NF2* patients have confirmed these findings (93,185). Inactivating mutations in the *NF2* gene have been detected in 20–30% of sporadic meningiomas, often accompanied by mutations or loss in the second allele (189,190). Schwannomin staining is absent in more than half of sporadic meningiomas (see earlier) (155,195).

Additional genes may be involved in meningioma pathogenesis on chromosome 22. A translocation (16a,68) observed in a meningioma cell line recently led to the identification of a gene, dubbed *MN1*, which is also involved in translocations with the *tel* gene in the pathogenesis of leukemias (200). This gene is centromeric but in close proximity to the *NF2* gene. What role *MN1* plays in the formation or progression of most meningiomas is still unresolved. Other genes more recently linked to meningiomas pathogenesis include *DAL1* and protein 4.1R (201).

In a screen of 81 meningiomas for mutations in the *NF2* gene, LOH for chromosome 22 markers was detected only in those meningiomas that also had *NF2* gene mutations (202). Of the 81 meningiomas, 44 had LOH of 22q, 29 had LOH of 1p, and 23 had LOH of 14q (202). The authors concluded that the formation of aggressive meningiomas follows a multistep tumor progression model involving genes on 1p, 14q, and 22q. Immunocytochemical studies of meningiomas support this hypothesis. Schwannomin immunoreactivity was absent in more than half the meningiomas, whereas the remainder showed strong schwannomin staining suggesting that the *NF2* gene was not mutated (155,195).

Genetic linkage studies provide further evidence for the existence of a second meningioma locus. Analysis of a pedigree with autosomal dominant meningiomas and ependymomas excluded the mutation from the *NF2* region (199). The region excluded by linkage analysis encompassed the region centromeric to *NF2* that contains the *MNI* gene.

**124.9.1.2 Chromosome 1.** Cytogenetic studies had indicated that next to loss of chromosome 22, deletions of chromosome 1p are common in meningiomas. Bello et al. (101) studied 50 meningiomas and identified 13 meningiomas with loss of chromosome 1 alleles, of which 12 had also lost alleles on chromosome 22. Most of these tumors showed aggressive growth. Analysis of 16 anaplastic meningiomas detected loss of chromosome 1p alleles at almost the same frequency as the loss of chromosome 22 (203), confirming the role of genes in 1p in the progression of meningiomas. Comparative genomic hybridization has shown that a meningioma locus maps to a distal chromosome 1p region (204). Analysis of 157 blood/tumor pairs showed LOH for 1p in 34% of cases, and high-resolution deletion mapping defined a 1.5 cM region within 1p32 as a candidate meningioma locus (205). More recently, loss of expression of the alkaline phosphatase *ALPL* that maps to 1p36.1-p34 was shown to be involved in meningioma progression (206).

**124.9.1.3 Chromosome 14.** There is considerable evidence supporting the existence of a meningioma locus on chromosome 14q. Aberrations including LOH on 14q are common in low- and high-grade meningiomas (202,207,208). As for changes in chromosome 1p alleles, alterations of the chromosome 14q locus may not be causative but rather related to in tumor progression, because many tumors also displayed LOH of the *NF2* locus (202,207).

This article is a revision of the previous edition articles by Kate MD Bushby, Lars Klinge, Anne Katrin Lampe, volume 3, pp 2928–2946, by Eugenio Mercuri, Cheryl Longman, and Victor Dubowitz, volume 3, pp 0000–0000, and by Alan H Emery, volume 3, pp 0000–0000, © 2007, Elsevier Ltd.

### GLOSSARY

**Becker muscular dystrophy** – an X-linked genetic condition, caused by mutations in the dystrophin (*DMD*) gene, leading to reduced production of the dystrophin protein within the muscle. Patients affected by Becker muscular dystrophy usually show first symptoms in their childhood or early teens, such as difficulties running or walking up stairs, frequent falls, and calf hypertrophy. Creatine kinase values are highly increased. Becker muscular dystrophy is a condition allelic to Duchenne muscular dystrophy.

**Muscle biopsy** – the removal of a sample of muscle tissue for histopathological examination or protein analysis in order to help with the diagnosis of a muscle condition.

**Calpain 3** – encoded by the *CAPN3* gene, calpain 3 is a calcium-dependent protease located both at the cytosol and the nucleus, with a possible role in regulating levels of muscle-specific transcription factors and muscle cell differentiation. Recessive mutations in the *CAPN3* gene are responsible for limb-girdle muscular dystrophy type 2A.

**Collagen type VI** – a microfibrillar protein forming a network that associates with other extracellular matrix proteins, with a role in stabilizing the myofibrils during contraction by anchoring the basement membrane to the interstitial extracellular matrix. Mutations in the genes encoding for three subunit chains of collagen VI are responsible for Ullrich congenital muscular dystrophy and for Bethlem myopathy.

**Congenital muscular dystrophy** – a muscle condition usually diagnosed at birth or shortly after, characterized by variable degrees of muscle weakness, increased creatine kinase values, and other associated features such as central nervous system involvement, eye abnormalities, and developmental delay. Congenital muscular dystrophies are caused by mutations in several different genes.

**Distal myopathy** – a muscle condition characterized by predominant distal involvement, i.e. of muscles of hands and feet.

**Duchenne muscular dystrophy** – an X-linked genetic condition caused by mutations in the dystrophin (*DMD*) gene, causing absence of the dystrophin protein within muscle. Patients affected by Duchenne muscular dystrophy usually show first symptoms in their childhood with difficulties running, walking up stairs, frequent falls and calf hypertrophy. Creatine kinase values are highly increased. Duchenne muscular dystrophy is a condition allelic to Becker muscular dystrophy.

**Dysferlin** – encoded by the *DYSF* gene, dysferlin is predominantly localized in the muscle membrane, playing an important role in muscle membrane maintenance and integrity, vesicle trafficking, phagocytosis, focal adhesion, and myogenic differentiation. Recessive mutations in the *DYSF* gene are responsible for limb-girdle muscular dystrophy type 2B and Miyoshi myopathy.

**Dystrophin** – a cytoskeletal protein encoded by the *DMD* gene, dystrophin is localized to the muscle cell membrane through a dystrophin-associated protein complex and acting as a mechanical link between the cytoskeletal actin and the extracellular matrix. Reduction or absence of this protein causes Becker or Duchenne muscular dystrophies.

**Dystrophin – glycoprotein complex** – a group of proteins forming a critical link between the inside and outside of muscle cells, essential for its structure and correct functioning. Mutations in genes encoding for members of this protein complex are responsible for different muscular dystrophies.

**Dystroglycanopathies** – a genetically heterogeneous group of muscle disorders, characterized by detection of hypoglycosylated  $\alpha$ -dystroglycan on muscle biopsy by immunolabeling and/or on western blot analysis. Dystroglycanopathies might clinically range from severe congenital muscular dystrophies to milder, later onset limb-girdle muscular dystrophies.

**Emerin** – encoded by the X-linked *EMD* gene, emerin is a nuclear membrane protein. Mutations in the *EMD* gene are responsible for the X-linked form of Emery–Dreifuss muscular dystrophy.

**Emery – Dreifuss muscular dystrophy** – a muscle condition mainly characterized by progressive muscle weakness, contractures, and cardiac defects, and caused by mutations in the *EMD*, *FHL1* (X-linked forms), and *LMNA* genes (autosomal dominant and recessive forms).

**Facioscapulohumeral muscular dystrophy** – muscle condition mainly characterized by weakness of the facial, shoulder, upper arm muscles. The conditions is slowly progressive and later may also involves other muscle groups and in particular the lower limbs. The condition is caused by a molecular defect on the short arm of chromosome 4.

**Gowers' maneuver** – a characteristic sign observed in presence of weakness of the pelvic girdle and proximal lower limb muscles. Patients use their arms and hands to push up on their legs to stand up from a lying position.

**Lamin A/C** – encoded by the *LMNA* gene, Lamin A/C is a major component of the nuclear lamina, a proteinaceous meshwork underlying the inner nuclear membrane. Lamin A/C is involved in several cellular and molecular processes of nuclear architecture, DNA synthesis, chromatin organization, gene transcription, cell cycle progression, cell differentiation, migration, and response to DNA damage. Dominant and rare recessive mutations in *LMNA* are responsible for different types of muscular dystrophies, cardiomyopathies, and other rare disorders also with no major cardiac or respiratory involvement.

**Limb-girdle muscular dystrophy** – muscle conditions characterized by weakness in the upper and lower girdle muscles. There are different types of LGMDs, classified according to their inheritance (dominant-LGMD1- and recessive-LGMD2-), and the underlying genetic defect.

**Merosin (laminin alpha 2)** – a protein encoded by the *LAMA2* gene and essential for maintaining the structure and function of muscles. Merosin protein is absent in biopsies from patients affected by congenital muscular dystrophy type 1A.

**Muscular dystrophy** – the term dystrophy derives from the greek words “dys” (“faulty”) and “trophe” (“nourishment”). Muscular dystrophy refers to progressive muscle conditions characterized by weakness and wasting of the voluntary muscles.

**Pseudohypertrophy** – typically observed in Duchenne muscular dystrophy, this term refers to prominence of muscles, in particular of calves, due to increased fat deposits rather than true hypertrophy of muscle tissue.

**Revertant fibers** – rare fibers observed in muscle biopsies from patients with Duchenne muscular dystrophy, showing positive labeling for dystrophin in presence of a mutation causing absent production of this protein. Revertant fibers are caused by second mutations in the *DMD* gene, giving rise to exon skipping and production of a shorter but functional dystrophin.

**Sarcoglycans** – encoded by the four sarcoglycan genes (*SGCA*, *SGCB*, *SGCD*, and *SGCG*), sarcoglycans are transmembrane proteins within the dystrophin-glycoprotein complex at the muscle cell membrane with possible role in stabilizing the membrane. Recessive mutations in the  $\gamma$ -sarcoglycan,  $\alpha$ -sarcoglycan,  $\beta$ -sarcoglycan and  $\delta$ -sarcoglycan genes are responsible for limb girdle muscular dystrophy types 2C, 2D, 2E, and 2F.

**Ullrich congenital muscular dystrophy** – a congenital muscular dystrophy caused by recessive mutations in the genes encoding for subunit chains of the collagen type VI protein. The condition is characterized by contractures of the proximal joints, marked distal laxity, hypotonia, and progressive scoliosis often associated with rigid spine. Maximum functional ability is variable.

**Walker-Warburg syndrome** – a form of congenital muscular dystrophy characterized by brain and eye abnormalities in addition to muscle weakness. Walker-Warburg syndrome is a highly genetically heterogenous disorder caused by recessive mutations in four different genes (*POMT1*, *POMT2*, *FKRP*, and *FCMD*).

## 125.1 INTRODUCTION

Muscular dystrophies are a group of inherited primary diseases of the muscle clinically characterized by muscle weakness and pathologically by abnormalities of muscle fibers. According to the most recent classifications (1) and publications, muscular dystrophies and their major differential diagnoses can be classified based on their inheritance and genetic defects, as shown in Table 125-1. A schematic representation of the proteins involved in the most common forms of muscular dystrophy is shown in Figure 125-1.

## 125.2 DYSTROPHINOPATHIES

### 125.2.1 Definition

Dystrophinopathies represent a wide spectrum of mild to severe progressive muscle diseases caused by mutations in the *DMD* gene. The well-recognized Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) represent the best-understood and most common diseases within this spectrum, affecting boys (and less frequently carrier females), and primarily causing skeletal muscles weakness. Isolated asymptomatic increase of creatine kinase (CK) values and cardiomyopathies represent the milder ends of the spectrum.

### 125.2.2 History

DMD is named after Guillaume Benjamin Amand Duchenne, a French physician who described this condition in 1861. However, an English physician, Edward Meryon, described the same disorder several years earlier. He noted that the disease affected males, segregated

**TABLE 125-1 Classification of Muscular Dystrophies**

Disease	Inheritance	Locus	Gene	Protein
DMD/BMD	X-R	Xq21.2	<i>DMD</i>	Dystrophin
FSMD type 1	AD	4q35	?	?
FSMD type 2	AD	4q35	?	?
EDMD X-linked type 1	X-R	Xq28	<i>EMD</i>	Emerin
EDMD X-linked type 2	X-R	Xq26.3	<i>FHL1</i>	Four-and-a-half LIM Domain 1
EDMD Autosomal Dominant	AD	1q21.2	<i>LMNA</i>	Lamin A/C

?: not known.

in families and essentially affected muscle, providing a detailed clinical, genetic, and pathologic study of the condition. In 1955, Peter Emil Becker delineated a milder form of X-linked muscular dystrophy, now referred to as BMD. In 1983, Davies et al. showed that the gene responsible for DMD was located on the short arm of the X chromosome, making prenatal testing available. The work from Harper et al. showed that BMD mapped to the same locus as DMD confirming these conditions were allelic. A few years later, cloning of the *DMD* gene

was accomplished by means of mapping of X chromosome translocations in manifesting female patients and use of deletion-detecting clones, and by 1988, specific DNA and protein-based diagnostics for dystrophinopathies was available.

### 125.2.3 Prevalence

DMD represents the most common inherited muscle disease of childhood, with an estimated point prevalence

**FIGURE 125-1** Schematic representation of the main proteins involved in muscular dystrophies, with their localization and reciprocal interactions. Disease names are indicated in abbreviations in underlined capital letters. Proteins are in lower case letters. *Reproduced with adaptation from Figure N. 1. of Straub and Bushby, 2006 (Straub and Bushby. The Childhood Limb-Girdle Muscular Dystrophies. Semin. Pediatr. Neurol. 13:104–114.)*

in northern England of 8.29/100.000 males (2), and birth prevalence of BMD of 1/18,450 live male births. It has been suggested that incidence rates of familial cases may be now declining as a result of prenatal testing (in countries where this service is offered to families with previous cases), leading in the long term to a relative increase of *de novo* cases. A high rate of new mutations maintains an essentially stable population frequency despite current practices of family counseling in identified families.

## 125.2.4 Duchenne Muscular Dystrophy

**125.2.4.1 Clinical Features.** DMD is mainly characterized by progressive, symmetrical muscle weakness affecting males, with an onset usually before the age of 5 years (3). A raised CK (typically up to  $>10$  the normal value) can be detected from birth. The most common first symptoms are walking delay ( $>18$  months of age) and general clumsiness compared to siblings and peers. Later, waddling gait, difficulties getting up stairs and from the floor (the so-called “Gower’s maneuver”), is caused by the presence of muscle weakness, affecting the pelvic girdle (Figure 125-2). The average age at diagnosis is 4–5 years (3). After this age, even in the context of a positive family history, a normal muscle examination greatly decreases the likelihood of a positive diagnosis, and this is highly unlikely above the age of 10. Some muscle groups and, in particular, the calves might appear enlarged (pseudohypertrophy), and muscle imbalances might cause contractures, in particular, shortening of the Achilles tendons. Flexion contractures of elbows, knees, hips and *talipes*

*equinovarus* can also develop after loss of ambulation. Muscle cramps and stiffness of the calf muscles are common, and myoglobinuria can also be observed. With no interventions, DMD patients are wheelchair bound before the age of 13 years. Respiratory muscle weakness and thoracic scoliosis contribute to respiratory insufficiency and together with cardiac involvement, in particular dilated cardiomyopathy and/or arrhythmias developing in the second decade, represent the most common causes of death. The intelligence coefficient is typically 1 SD below the general population, but cognitive impairment is not progressive and not correlated with weakness. Verbal intelligence and verbal skills appear more affected than performance. Smooth muscles can also be involved with occasional bladder paralysis, paralytic ileus, and gastric dilation. Delayed puberty and low bone mineral density is also observed (3–5).

**125.2.4.2 Natural History.** DMD shows a predictable clinical course in the absence of treatment. Independent ambulation is lost around the age of 9 years and, by definition, by the age of 13 years. Progression of muscle weakness to further muscle compartments and organs results in scoliosis, respiratory and cardiac impairment. The mean age at death in the absence of interventions is around age 19 years, 90% attributable to respiratory and 10% to cardiac causes.

## 125.2.5 Becker Muscular Dystrophy

BMD is also characterized by progressive symmetrical muscle weakness, often associated with calf hypertrophy, but onset is usually later than in DMD (mean age 11) (6),

**FIGURE 125-2** The sequence of the Gower's maneuver in a boy affected by Duchenne muscular dystrophy. (Figure by courtesy of Richard S. Finkel, Director of the Neuromuscular Program, The Children's Hospital of Philadelphia.)

and some patients show onset of mild symptoms only in late adulthood. Calf pain and cramps, in particular during and after exercise, is commonly observed and often represents the major symptom at onset. CK values are increased, usually up to  $>5$  times the normal values. Progression of weakness is slower than in DMD, and ambulation is longer preserved, and wheelchair dependency develops per definition after the age of 16 years and often very much later. Contractures of Achilles tendons are commonly observed. Cardiomyopathy is a common finding in BMD with cardiac symptoms also sometimes occurring before the onset of weakness, and it represents the cause of death in up to 50% of patients (7).

### 125.2.6 Manifesting Carriers of Dystrophinopathies

Heterozygous female carriers of *DMD* gene mutations are mostly asymptomatic; however, between 2.5 and 7.8% of carriers develop some symptoms of the condition (manifesting carriers—MCs) ranging from very mild late-onset muscle weakness to a rapidly progressive DMD-like phenotype (8). Asymmetry of weakness is a common finding and likely related to somatic mosaicism. Cardiomyopathy is also common, with positive echocardiographic evidence in up to about 36–38% of MCs. Decline in cardiac function can be acute, in particular, during pregnancy,

making monitoring of cardiac function pivotal for MCs. CK values are elevated up to 2–10 times the normal values in around 50% of females with a truncating *DMD* mutation and in around 30% of females with in frame changes.

### 125.2.7 *DMD* Gene-Associated Dilated Cardiomyopathy

Isolated dilated cardiomyopathy caused by *DMD* gene mutations is characterized by predominant involvement of cardiac muscles, with relative sparing of skeletal muscles, occurring in both males and females. Males, usually symptomatic between ages 20 and 40 years, show a more severe and progressive phenotype, and cardiac transplant is frequently recommended. CK values are elevated, and on muscle biopsy analysis myopathic changes can be observed.

### 125.2.8 Genetics and Pathogenesis

Dystrophinopathies are X-linked conditions caused by mutations in the dystrophin (*DMD*) gene.

**125.2.8.1 The Dystrophin Gene.** The *DMD* gene is located on chromosome Xq21.1 and spans 2.4Mb of genomic DNA, being the largest known human gene. The coding sequence of 11 kb represents only 0.6% of the entire gene, and it is divided in 79 exons with multiple promoters.

**125.2.8.2 The Dystrophin Protein.** The dystrophin protein has a molecular weight of 427kDa and consists of 3685 amino acids. Dystrophin is an N-terminal actin-binding protein, with 24 spectrin-like repeat units interspersed by four hinge regions, followed by a cysteine-rich domain and a C-terminal domain. The N-terminal domain has three actin-binding sites with a fourth one located within the 11–17th spectrin-like repeats. Dystrophin is a cytoskeletal protein, localized to the muscle cell membrane through a dystrophin-associated protein complex and acts as a mechanical link between the cytoskeletal actin and the extracellular matrix (Figure 125-1). Its C-terminal cysteine-rich domain binds to the  $\beta$ -dystroglycan, which via the transmembrane  $\alpha$ -dystroglycan is connected to the extracellular matrix protein laminin  $\alpha$ -2. The dystrophin protein is also a key mediator in the communication between the extracellular matrix and the cytoskeleton. There are different known isoforms of the protein, and each isoform is under the control of one of the different promoters, with shorter transcripts being generated from internal promoters. Full-length proteins are found in the muscle, brain and Purkinje cells. Shorter brain isoforms have been implicated in mental retardation, while mutations in the muscle promoter and first exons are related to the isolated forms of cardiomyopathies.

**125.2.8.3 *DMD* Gene Mutations.** A large spectrum of *DMD* gene mutations has been described so far, including

deletions of the entire gene, deletions/duplications of one or more exons, small deletions, insertions, or single base changes. Probably due to its extreme size, the mutation rate is higher than the estimated average mutation rate in humans ( $1.10^{-4}$  versus  $10^{-5}$ – $10^{-6}$  for human genes) with about 1/3 of all mutations being *de novo* changes with more than 4700 different mutations described so far (9). Mutation hot spots are recognized with partial deletions and duplication mutations clustering in two recombination hot spots, one proximal to the 5' end of the gene involving exons 2–20 ( $\approx 30\%$  of the mutations), and one more distal, involving exons 44–53 ( $\approx 70\%$  of mutations). Duplications cluster near the 5' end of the gene, with duplication of exon 2 being the most common duplication (9). The reading frame rule was first described by Monaco et al. in 1988, giving an explanation for the phenotypic difference between DMD and BMD. Mutations identified in DMD patients are shown to affect the translational open reading frame (ORF) of triplet codons, and each mutation is predicted to result in truncated abnormal products, while mutations identified in BMD patients maintain the translational ORF. An in-frame deletion will produce a shorter lower molecular weight and semifunctional protein giving rise to a milder clinical phenotype. The same ORF mechanism is also applicable for splice site mutations. About 10% of known mutations do not follow the reading frame rule, and this could be explained by mechanisms holding true the reading frame rule at the RNA level (9). In particular, missense and also in-frame deletion/duplication mutations can affect splicing and thus create out-of-frame transcripts, while large in-frame deletions may result in nonfunctional product, especially if they involve key domains such as the cysteine-rich domain. Conversely, nonsense mutations and out-of-frame deletions/duplications can also affect splicing, leading to in-frame transcripts and, therefore, BMD phenotypes. These events have been observed in about 2% of BMD patients (9). Finally, a number of mutations have been identified in both DMD and BMD patients, and again it has been suggested that this could be caused by alternative splicing of one of more flanking exons or use of alternative translation initiation codon, such as the three in-frame start codons in exon 8. mRNA analysis is currently not always feasible, and predictive softwares, such as ESEfinder, can help to identify exonic splicing-enhancer sequence motives to further define the effect of novel *DMD* mutations. Report of families segregating the same *DMD* mutations in family members showing different phenotypes indicate that other factors can also play a role and part of this clinical variability could possibly be explained by transacting polymorphisms, e.g. within muscle performance genes or splicing factors as well as cis-acting polymorphisms in the *DMD* locus itself.

**125.2.8.4 Pathogenesis.** The most likely sequence of events in the pathogenesis of DMD and BMD is that the deficiency of dystrophin (and the resulting reduction of all the dystrophin-associated proteins) causes a disruption

of the cell membrane and an efflux of muscle proteins (e.g. CK) and an influx of calcium. The latter leads to mitochondrial overload with ATP depletion, decreased oxidative phosphorylation, and cell death (muscle cell necrosis). An imbalance between muscle fiber necrosis and regeneration is considered the main cause of the clinical manifestations of dystrophinopathies, with the primary pathologic feature necrosis, and with decrease of regenerative capacity with age, leading to replacement of muscle fibers with connective and adipose tissue (10). Several aspects of the pathogenesis of dystrophinopathies are far from clear. In particular, the cause of the delay in onset and the thereafter-progressive nature of the diseases remain hard to explain.

Several different pathophysiological hypotheses have been described in more detail elsewhere (10). Currently, the mechanical and the impaired calcium homeostasis hypothesis represent the two main leading hypotheses. In addition, a contribution of inflammation, apoptosis, and regeneration has also been suggested. According to the mechanical hypothesis, absence of dystrophin affects the membrane structure. Concurrent delocalization of dystrophin-associated proteins from the membrane leads to membrane fragility and increased membrane permeability, all greatly affected by exercise. Structural weakness and tears in the sarcolemma and consequent fail in membrane repair cause influx of calcium-rich extracellular fluid. When the calcium-buffering capacities of the sarcoplasmic reticulum, the mitochondria and intracellular calcium-binding proteins are reached, calcium-dependent proteases are activated leading to digestion of cytoskeletal and myofibrillar proteins, together with activation of calcium-mediated phospholipases that further damage the membrane. Dystrophin deficient cells have an inherent defect in calcium regulation also in the presence of the intact plasma membrane, due to increased opening of calcium leak channels. An increased calcium level makes mitochondria form a large pore complex, leading to loss of matrix and intermembrane contents, and to mitochondrial swelling, rupture and then necrosis and apoptosis. Increased influx of extracellular fluid also causes intracellular activation of complement, leading to further damage of intracellular membranous organelles and recruitment of macrophages. Interestingly, glucocorticoid treatment in DMD has been shown to decrement the number of inflammatory cells, but the beneficial effect of the treatment is unlikely related to its antiinflammatory effect. Oxidative stress has also been implicated in DMD pathophysiology, as *mdx* mice muscles show increased levels of antioxidant enzymes even before onset of myopathology. Oxidative stress combined with additional insult to the cell homeostasis such as a physical damage could promote cell pathology. Sparing of extraocular muscles could be attributed to better calcium handling capability, higher utrophin levels, and smaller size of muscle fibers that can influence the tension exerted on the plasma membrane.

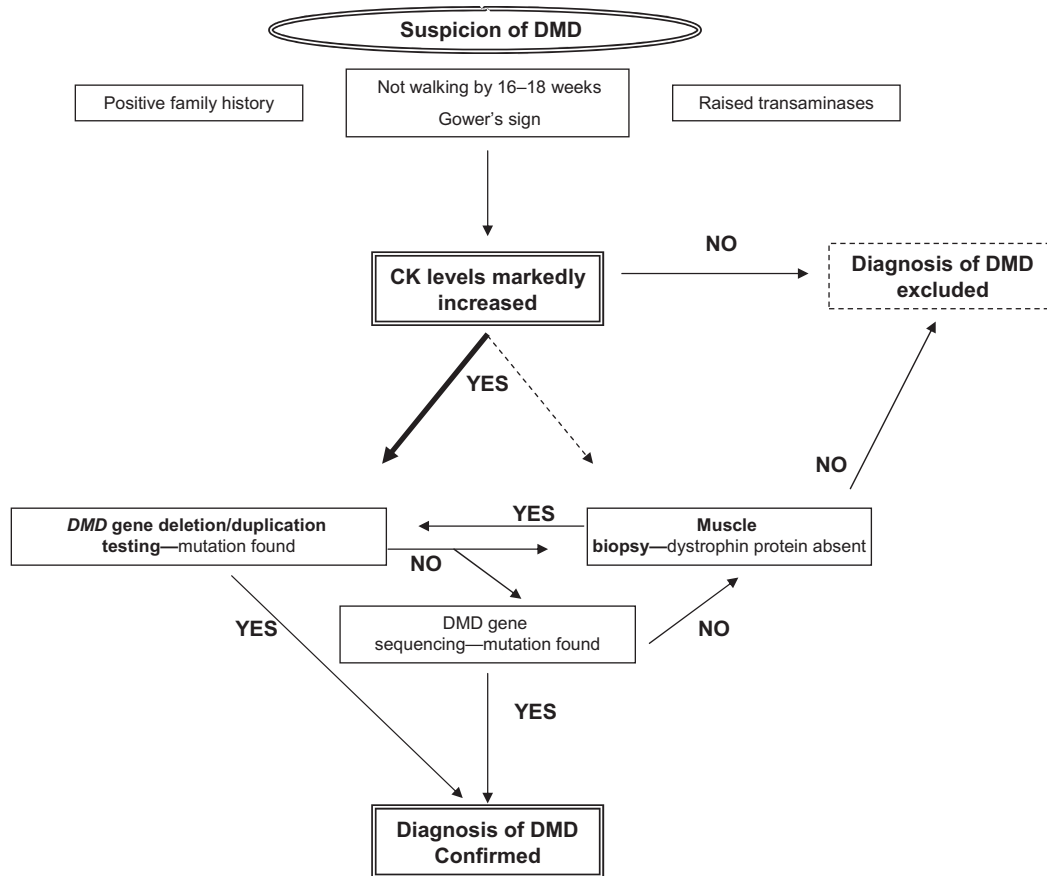

### 125.2.9 Diagnosis

Diagnosis of dystrophinopathies and in particular of DMD should be suspected in any child with a positive family history but, as new mutations are so commonly seen, also in the case of (A) a male child with abnormal muscle function such as delayed walking (>16–18 months of age), frequent falls, difficult running, and climbing stairs, Gower's maneuver, waddling gait; (B) increased CK values; and (C) increased transaminases. In the case of a positive family history, increased CK values would be indicative of a positive diagnosis. Speech and language delay also supports positive diagnosis (4,5).

Diagnostic algorithms include clinical and genetic investigations that should be done and interpreted together (Figure 125-3). In the case of abnormal muscle function in a male child, increased CK levels should prompt *DMD* gene analysis, with deletions/duplications analysis as first step, preferably by a technique that screens all exons such as multiplex ligation-dependent probe amplification (MLPA) (11). Presence of a mutation in the *DMD* gene confirms a diagnosis of dystrophinopathy. If no mutations are found, a muscle biopsy can confirm the absent dystrophin labeling on immunohistochemistry that should prompt direct sequencing of the gene. If the muscle biopsy analysis shows normal protein labeling, alternative diagnoses should be considered, although very rare cases of DMD and BMD probably do have normal localization of protein. Many other forms of muscular dystrophy (for example some forms of limb-girdle muscular dystrophies (LGMDs) or congenital muscular dystrophies) cause an elevated CK, so the finding of an elevated CK without confirmatory tests should never be considered diagnostic of dystrophinopathy. It is important to note that dystrophinopathy is much more common than other forms of muscular dystrophy, so the diagnosis should always be considered seriously (for example, in sporadic female cases, the diagnosis of MC is important to consider, and BMD is much more common than the different forms of LGMD).

The test most commonly used to identify deletions/duplications of the *DMD* gene mutations is MLPA; however, other techniques such as multiplex amplifiable probe hybridization and single condition amplification/internal primer are also available, and the latter also provides sequence data alongside deletions (11–14). If these tests are negative, full *DMD* gene sequencing should be performed in order to identify point mutations and small deletions/insertions (15). As none of these techniques is 100% sensitive and universally available, muscle biopsy can facilitate diagnosis and, in yielding a quicker diagnosis, minimize anxiety of the families (16). An open biopsy is necessary so that adequate tissue amount is available, in particular if alternative diagnoses need to be considered as well. Cocothome technique has the advantage of providing a larger sample compared with single-core needle biopsy and does not require open surgical procedure (17).

**FIGURE 125-3** Diagnostic approach in case of suspicion of Duchenne muscular dystrophy (DMD).

A muscle biopsy alone in absence of confirmed genetic result is not sufficient to confirm a diagnosis of dystrophinopathy and crucially is not sufficient to offer the carrier testing, which is then mandatory to suggest for the rest of the family. Noteworthy, in the presence of positive genetic testing, muscle biopsy is not required to confirm the diagnosis, although some centers may like to perform dystrophin quantification in conjunction with the genetic testing and clinical assessment.

**125.2.9.1 Other Clinical Investigations.** Recent recommendations for diagnosis and care indicate that electromyography (EMG) and nerve conduction studies are not necessary for the specific assessment of DMD (4,5). In fact, EMG analysis shows nonspecific findings observed in all myogenic disorders, and it is therefore of relative inutility in the diagnostic process of dystrophinopathies.

**125.2.9.2 Muscle Biopsy and Protein Analysis.** Muscle histology in the early stages of the disease shows nonspecific dystrophic changes such as variation in fiber size, foci of necrosis, and regeneration and hyalinization. In later stages, deposition of fat and connective tissue is evident. Necrotic fibers are surrounded by macrophages and CD4+ lymphocytes. Small internally nucleated fibers reflect muscle regeneration. Immunohistochemistry analysis shows complete or almost complete absence of dystrophin in DMD,

and dystrophin is typically not detectable on Western blot analysis (Figures 125-4 and 125-5) (4,5). In BMD, labeling of dystrophin can appear normal, patchy, or reduced on immunohistochemistry, while Western blot analysis could show bands of normal or abnormal weight and quantity (Figures 125-4 and 125-5). Dystrophin abundance could be studied by immunohistochemical techniques, and Western blot analysis is able to offer valuable semiquantitative data (16). Recently, a method has been developed to quantify relative levels of sarcolemma-associated proteins using digitally captured images of immunolabeled sections of skeletal muscle (18). This method appears useful not only to establish both the abundance and localization of dystrophin but also to assess the efficacy of experimental therapies leading to partial dystrophin restoration or upregulation (18).

Female carriers typically show a mosaic pattern of immunohistochemistry, with variable amounts of protein on Western blot, depending on the mutation and the amount of X-chromosome inactivation, although these changes may be subtle (Figure 125-5). Electron microscopy (EM) is not required for diagnosis of dystrophinopathies.

**125.2.9.3 DNA Analysis.** Molecular confirmation of dystrophinopathies is achieved when a clearly pathogenic *DMD* gene sequence variant is found in an affected

**FIGURE 125-4** Main muscle immunohistochemical findings in patients with muscular dystrophies. Control staining for Dystrophin,  $\alpha$ -dystroglycan, Caveolin 3, Desmin, and Myotilin are in panels A, C, E, G, and I respectively; (B) dystrophin staining in a female carrier for DMD; (D)  $\alpha$ -dystroglycan staining in a LGMD2I patient with *FKRP* gene mutations; (F) Caveolin-3 staining in a patient with LGMD1C; (H) Desmin staining in a patient with *DES* gene-related MFM; (J) Myotilin staining in a patient with *MYOT* gene-related MFM. (Figure courtesy of Dr Rita Barresi, NCG Diagnostic and Advisory Service for Rare Neuromuscular Diseases, Muscle Immunoanalysis Unit, Newcastle upon Tyne, UK.)

individual (19). The current recommended diagnostic workup of dystrophinopathies is shown in the algorithm in Figure 125-3. If a deletion/duplication is found, a diagnosis of BMD or DMD is made according to the reading frame and the overall clinical presentation.

Where duplication is detected, the prediction of the reading frame is not feasible with genomic analysis only, as the determination of the orientation of duplicated exons requires mRNA analysis.

If no mutation is found, the likelihood of the diagnosis is reduced depending on the sensitivity of the screening technique. Since none of the current molecular tests is 100% sensitive, it is not possible to refute a diagnosis if no mutation is found. Indeed, recent reports show that about 4–7% of symptomatic individuals show no detectable mutation by genomic analysis, and analysis of mRNA or muscle biopsy analysis would be required to confirm the diagnosis in these patients (14).

### 125.2.10 Prevention and prenatal testing

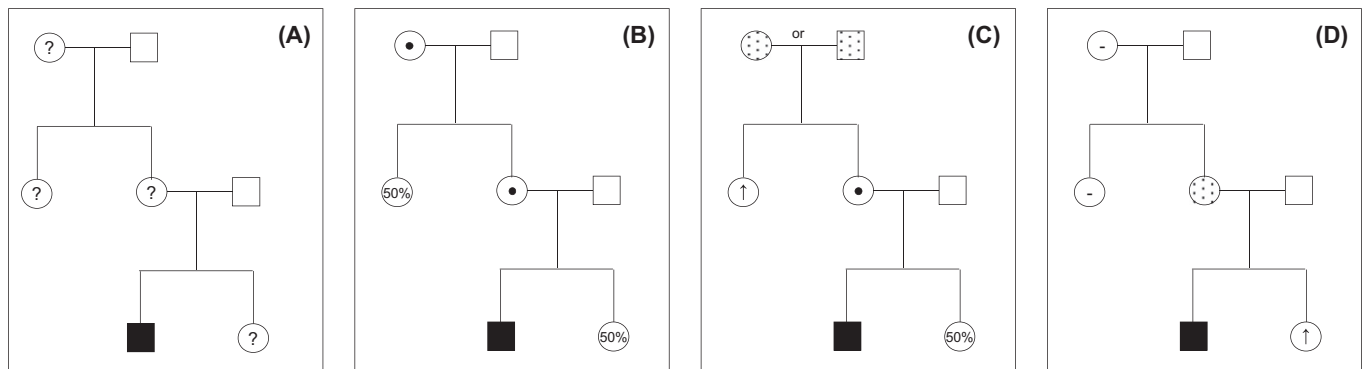

Prevention of dystrophinopathies is possible by means of counseling and prenatal diagnosis.

**125.2.10.1 Genetic Counseling.** Dystrophinopathies are X-linked conditions. Fathers of affected males are therefore not affected nor carry the mutation. Mothers and other relatives from the maternal line are at risk of being affected or being carriers for the disease (Figure 125-6). A woman with more than one affected son is either a carrier or has germ line mosaicism for the disease-causing mutation. If the proband is the only affected individual in the family, the mother is either a carrier or the mutation is occurred *de novo* in the egg or sperm at time of conception (germ line mutation) (20). The mother could also present mosaicism (somatic or germ line) for the mutation. If the mother is a carrier, she could have inherited this mutation from her mother (maternal grandmother of the affected individual) who could be either a carrier or a somatic mosaic, or have had germ line mosaicism or a *de novo* mutation (these last two options also valid for the maternal grandfather). The risk for the sibs of affected individuals depends on the carrier status of the mother, although also needs to take into account germ line mosaicism (Figure 125-7) (20). If the mother is a carrier, the risk of transmitting the disease mutation is 50% for each pregnancy. Males affected by dystrophinopathies have no risk of transmitting the disease to their male offspring, while their daughters will be obligate carriers.

**125.2.10.2 Carrier Testing.** About 2/3 of cases of dystrophinopathies are transmitted from carrier females, and testing of mothers and sisters is therefore fundamental not only because of counseling issues but also to identify potential MCs. Prior identification of the disease-causing mutations in the affected individuals is crucial in testing potential at risk relatives. When the mutation is known, screening of the disease-causing mutation can be performed on a DNA sample from the at-risk relative. About one-third of the potential carriers are still not tested and therefore missed, and discussion about the indication of a more active approach of at risk family members is in progress (21). If the affected male

**FIGURE 125-5** Schematic representation of the main muscle Immunoblot findings in patients with muscular dystrophies. Specific protein labeling is indicated on the left side of the image. Protein weights of each fragment are indicated in kDa on the right side of the image. The first lane represents the control muscle. The following lanes represent patients affected by (from left to right) BMD due to an in-frame duplication of the *DMD* gene; BMD due to an in-frame deletion of the *DMD* gene; DMD; LGMD2B, LGMD2D and LGMD2A. The last lane represents an example of a patient with confirmed diagnosis of LGMD2A, based on clinical and molecular data, with normal Calpain 3 labeling on immunoblot. (Figure courtesy of Dr Rita Barresi, NCG Diagnostic and Advisory Service for Rare Neuromuscular Diseases, Muscle Immunoanalysis Unit, Newcastle upon Tyne, UK.)

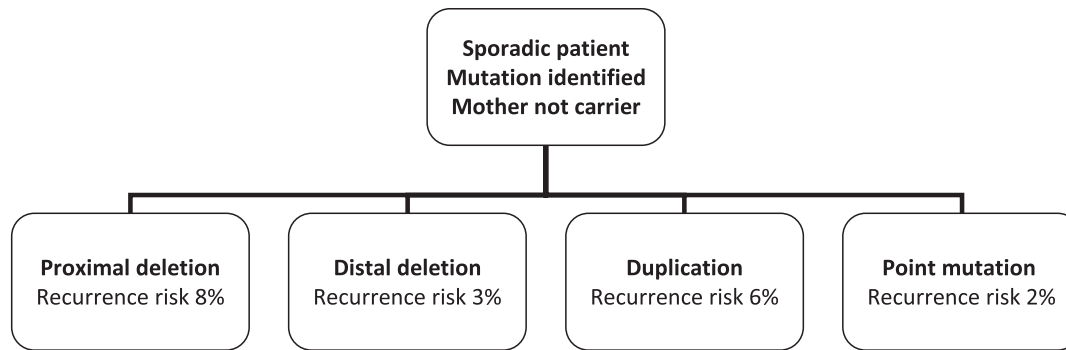

**FIGURE 125-6** Carrier status and germ line mosaicism in DMD. Dotted circles/squares represent males and females with germ line mosaicism. (A) In the case of a sporadic affected male, females through the maternal line are at risk of being somatic carriers. (B) In case the mother is a carrier, the sister of the affected has 50% risk of being carrier. If the maternal grandmother is also a carrier, the maternal aunt has a 50% risk of being a carrier. (C) If the grandmother is not a carrier, there is a low residual risk due to germ line mosaicism in the grandparents for the maternal aunt of being a carrier. (D) In case the mother is not a carrier, there is low residual risk due to germ line mosaicism for the sister of the affected of being a carrier.

relative is not available, at-risk females should be tested as discussed for affected individuals.

In the case of an unknown *DMD* mutation, the presence of signs and symptoms of the disease in at risk relatives could also help to estimate carrier status and genetic counseling. The Bayes' theorem has for a long time been a valuable tool to calculate carrier risk in case of a single child affected by dystrophinopathy with no mutation

found and depending on CK values. The Bayes' theorem is based on the prior, conditional, joint, and posterior probabilities of the mother being a carrier. The prior probability is based on the knowledge of the antecedents and sibs, and the conditional probability is the probability of being carrier or not depending on the CK values of the mother and the number of unaffected sons she might have. The product of the prior and the conditional

**FIGURE 125-7** Recurrence risk in case of a sporadic patient affected by Duchenne muscular dystrophy, with the mother not being a carrier. The indicated risks are for an affected son only and with no information about the haplotype. (Reproduced with adaptation from Figure N. 3 of Helderma-van den Enden et al. (20).)

probability is the joint probability, while the posterior probability of a woman to be carrier for dystrophinopathy is the joint probability of being carrier divided by this plus the joint probability of non being a carrier (3).

**125.2.10.3 Haplotype Analysis.** Where there are multiple affected individuals in the same family, and in the case of a clearly defined clinical diagnosis with no living relatives for direct carrier testing, haplotype analysis could be offered by some laboratories to trace the at-risk DMD haplotype for carrier testing and prenatal diagnosis. At least, three informative markers should be used, one of which is intragenic and one extragenic flanking the DMD gene on either side. Interpretation needs to take into account recombination risk, and therefore it is not in common use, now that direct methods of mutation detection have become more widespread.

**125.2.10.4 Germ Line Mosaicism.** About 1/3 of patients with dystrophinopathy show a *de novo* DMD gene mutation that occurred during cell division (mitosis or meiosis). As the general mutation rate is relatively low, the risk of a second independent mutational event in a family or individual is estimated to be low. Germ-line mosaicism was first described in DMD in the late 80s, and at that time, the recurrence risk for noncarrier females was estimated to be between 14 and 20%. Recent data suggest that the real estimate of recurrence risk in case of *de novo* DMD mutation is much lower, being 8.6% (4.8–12.2), if the risk haplotype is transmitted (20). In the current counseling practice where risk haplotype is not usually investigated, the recurrence risk is estimated to be 4.3%. This increased risk also applies for sisters of apparently *de novo* carrier females because of germ line mosaicism in the maternal grandmother or grandfather that could cause an increased risk of being carrier themselves and therefore of transmitting the disease. Remarkable differences have been noted if the mutation is a proximal (15.6%) or distal deletion (6.4%) (Figure 125-7) (20). Most mutations, and in particular deletions, originate on the X-chromosome of the maternal grandmother, whereas point mutations originate on the X-chromosome of the maternal grandfather. Germ line mosaicism should therefore be considered when

counseling families with *de novo* DMD mutations and prenatal diagnosis should be discussed in all pregnancies of mothers of isolated cases and carrier testing for their sisters (20).

**125.2.10.5 Prenatal Testing.** Prenatal testing is offered in case of male pregnancies to females who are known to carry a DMD gene mutation or who are at risk of germ line mosaicism for known DMD gene mutations. The procedure usually involves extraction of DNA from fetal cells (chorionic villi at 10–12 weeks' gestation or amniotic cells at 15–18 weeks' gestation). In the case of an unknown mutation, linkage analysis could also be offered; however, this should take into account the high risk of recombination. Currently, it is not possible to predict if a carrier female will manifest any signs or symptoms of the disease, and therefore, it is generally considered inappropriate to offer prenatal testing in case of female fetus. Examination of possible maternal cell contamination of the fetal DNA must be carried out as this, in particular with specific type of mutations such as deletions, could affect the interpretation of the test giving false negative results. Preimplantation genetic diagnosis (PGD) is offered in a limited number of centers throughout the world and special requirements apply (22).

**125.2.10.6 Neonatal Screening.** In the case of suspicion of dystrophinopathy at birth, such as grossly elevated CK values at birth or because of a positive family history, genetic testing can be performed at an early stage, allowing early institution of treatment and prompt genetic counseling. Currently, some countries are performing newborn CK screening programs, and this is currently considered also by other countries in view of possible future presymptomatic treatments (23). This sort of screening program holds several ethical and practical implications that need further discussion (24,25).

## 125.2.11 Management and Treatment

To date, there is no curative treatment for dystrophinopathies. Over recent years, advances in medical management and treatment of complications of dystrophinopathies have made a significant difference in terms

of natural history of the disease and also in terms of life expectancy, in particular, for DMD. The key interventions for DMD are use of steroids, surgical management of scoliosis, management of cardiac and respiratory complications as well as enhancement of quality of life, with timely supply of aids, adaptations, and access to independent living (26). All affected individuals should have access to the same clinical care, and nihilistic approach should not be accepted. In 2009, the international “DMD care considerations working group” evaluated assessments and interventions used in the management of DMD and developed care recommendations for this condition. These recommendations represent a framework for a coordinated multidisciplinary care, including rehabilitation, gastroenterology, nutrition, orthopedic, surgical, respiratory, and cardiac cares (4,5).

Benefits of steroids on DMD were first suggested in 1974, and glucocorticoids still represent the gold standard in DMD care, being the only currently available medication able to slow down the disease progression in terms of muscle strength and function. This also reduces risk of scoliosis, stabilizes respiratory function and improves cardiac function. Randomized control trials (RCTs) showed that treatment with 0.75 mg/kg of prednisone/prednisolone improves muscle strength, being daily regimes more effective than alternate (4,5,26–28). Deflazacort, a sodium-sparing glucocorticoid used in Europe but not approved in the US, has been shown to have a similar efficacy at a daily dose of 0.9 mg/kg and associates with lower risk of side effects (29). Long-term use of glucocorticoids prolongs ambulation and reduces speed of muscle function decline. Particular care need to be taken for steroid-related side effects and their prevention, and management has to be proactive. A multicenter, double-blind, parallel-group study, aiming to compare three steroid regimes (prednisone 0.75 mg/kg/day, prednisone 0.75 mg/kg/10 days on 10 days off, deflazacort 0.9 mg/kg/day) is currently underway in order to assess whether daily steroids are of greater benefit than intermittent steroids, and whether deflazacort does indeed associate with a better side effect profile than daily prednisone (30). At the moment, there are no evidence-based guidelines regarding when to start glucocorticoid treatment. Current consensus suggests that unless there are major preexisting risk factors for side effects, steroid treatment should be proposed when the child reaches the so-called *plateau* phase (age 4–8 years) when there is no progress in motor skills but prior to decline of muscle function, as evidenced by history and timed testing (4,5).

Anabolic steroids are neither necessary nor appropriate. There are no clear recommendations for use of creatine in DMD, and a RCT of creatine in DMD did not show clear benefits. Coenzyme Q10, amino acids, antiinflammatories, antioxidants, and potential disease modifying drugs, such as pentoxifylline and herbal and botanic agents, have been used or indicated for DMD treatment, but there are no supportive data to corroborate their use (4,5).

Due to the much less-progressive clinical course seen in most cases of BMD, steroids are much less frequently used. Cardiac and respiratory surveillance and timely intervention (including for some patients cardiac transplantation and ventilator support) are the mainstay of management along with physiotherapy and timely provision of aids and adaptations.

**125.2.11.1 Molecular Therapies.** Different molecular strategies, such as cell and gene therapy, mutation specific and cellular pathway approaches have been tested in cell lines, animal models, and clinical trials. At the current time, stem and progenitor cell therapies appear more distant from therapeutic applications (31–33). This field by definition is moving very rapidly, and the following is a summary of the state of the art at the time of writing—with the results of ongoing trials, there will be new findings in this area in the coming years.

**125.2.11.1.1 Gene Replacement Therapy.** The main obstacle for gene replacement is the size of the DMD gene and the difficulty of fitting it in gene transfer vehicles, such as adeno-associated virus. Mini or microdystrophins are able to transfer in adenovirus, and in *mdx* mouse, they give rise to robust gene expression correcting the muscle defect. However these approaches result more difficult in humans because of unpredicted obstacles such as immune response that requires further studies (34). Human artificial chromosomes containing the entire dystrophin genome with patient-derived and induced pluripotent stem cells and artificial zinc finger transcription factors targeting the utrophin gene promoter have been also proposed as alternative approaches, offering lower risk of immunorejection. Finally, utrophin upregulation has been modeled in various ways, and this approach could add beneficial effects if combined with other treatments.

**125.2.11.1.2 Mutation Suppression or Stop Codon Read Through.** Aminoglycoside antibiotics possess the unique property to read through stop codons in pro- and eukaryotes, introducing a nucleotide sequence at the mRNA level that creates a missense mutation instead of the stop codon that permits the translation of the full-length protein. Gentamicin-induced mutation suppression was observed in the *mdx* mouse, with expression of full-length protein and reduction of serum CK. This mutation suppression treatment would potentially be applicable only for patients with mutations leading to premature termination codons that in humans represent 13–15% of all DMD/BMD cases. Treatments with gentamicin showed that in order to achieve efficacy in restoring muscle function, doses would need to be increased with potential renal and auditory toxicity (35,36).

PTC124 (Ataluren, PTC therapeutics, South Plainfield, NJ, USA) is a 284-Da, 1,2,4-oxadiazole-linked furobenzene and benzoic rings drug that have been designed to readthrough stop codon mutations, and its therapeutic application are currently underway for cystic fibrosis and hemophilia. A phase IIb clinical trial with

Ataluren in DMD/BMD showed no statistically significant change in the primary endpoint of the trial (6-minute walking test) within the 48 weeks duration of the trial; however, the drug has been shown to be safe (<http://www.clinicaltrials.gov>). Discussion is currently in progress about the real efficacy of PTC124 to readthrough stop codons, and it has also been suggested that this agent could reactivate silent retroelements with potential negative consequences in future generations (37).

**125.2.11.1.3 Exon Skipping and Antisense Oligonucleotides.** The exon skipping approach is based on the observation of rare dystrophin-positive revertant fibers in muscle biopsies from DMD patients. This phenomenon is caused by spontaneous second mutations that cause exon skipping, giving rise to restoration of the reading frame and therefore production of shorter but functional dystrophin. This approach is based on direct manipulation of the dystrophin transcript, via antisense oligonucleotides (AONs), chemically synthesized single-strand DNAs designed to hybridize with a complementary sequence of mRNA, able to alter RNA process excluding one or more exons from the mRNA. When appropriately designed, AONs are able to restore the reading frame leading to a partially functional dystrophin protein (38–41). Feasibility of exon skipping has been demonstrated by local and systemic administration of AONs in mice, CXMD dogs, and utrophin/dystrophin double-ko mice. Study of proof of principle and safety of exon 51 skipping with 2 different backbones (2-O-methylAONs-PRO051 and morpholino AONs-AVI-4658) following intramuscular injections, demonstrated partial restoration (3–35% expression) and sarcolemmal localization of newly synthesized dystrophin (42). Phase I/II studies of intravenous infusions of AVI-4658 and subcutaneous administration of PRO051 have been recently performed to evaluate their safety profile first and then their ability to induce exon skipping and dystrophin expression. Both studies showed variable dose-dependent systemic restoration of dystrophin (43,44). Moreover, PRO051 administration also showed a modest anecdotal improvement in the 6-minute walk test. Preliminary results appear promising, and current molecular data indicate that up to 60% of DMD patients would potentially benefit from single-exon skipping approach. Single- and double-exon skipping would be applicable to 79% of deletions, 91% of small mutations, and 73% of duplications, amounting to 83% of all DMD mutations. Exon 51 skipping alone would be applicable up to 13% of all DMD patients (45). Multiexon skipping approaches would have the benefit of covering large number of mutations and patients with a single treatment. The open question is whether partial restoration of dystrophin expression is sufficient to induce clinical and functional improvement and different chemistries with improved delivery systems are currently in study. Worth mentioning, none of these therapies are currently able to target the heart in the *mdx* mouse at clinical doses, and ways to overcome this are currently explored.

## 125.3 FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

Facioscapulohumeral muscular dystrophy (FSHD) is a dominantly inherited muscular dystrophy and represents the 3rd most common muscular dystrophy after dystrophinopathies and myotonic dystrophy, with an estimated prevalence of 1–15.00/20.000 (46,47).

### 125.3.1 Clinical Features

FSHD is characterized by typical distribution of muscle weakness that usually begins involving the facial muscles, and it is often mild and asymmetric. Subsequently, weakness involves the scapular, humeral, truncal, and lower extremity muscles, and it often keeps its prominent asymmetric pattern. Pain and/or fatigue are common complaints occurring in up to about 70% of the individuals (48). Abdominal muscle weakness is often observed. Clinically relevant respiratory dysfunction occurs in less than 1% of patients, while cardiac involvement, in particular atrial arrhythmias, is observed in about 5% of patients, although only a few require treatment. Mild high-frequency hearing loss occurs in up to 75% of patients, and it appears more profound in patients with infantile onset. Retinal vasculopathy is frequent but rarely leads to a symptomatic exudative retinopathy (Coats' syndrome), which can in turn result in significant visual loss (47).

FSHD shows some clinical variability between patients and also within families. The condition appears more severe in males than females and penetrance also shows sex difference (49). By age 30 years, penetrance is 95% for males and 69% for females. Somatic mosaicism is common (50) and can considerably affect clinical presentation and recurrence risks. Somatic mosaicism often associates with absence of symptoms, in particular in females, while mosaic male subjects can show a milder phenotype. Offspring of a mosaic individual will likely show a more severe phenotype than expected based on the clinical presentation of the mosaic parent, explaining cases of anticipation observed in some FSHD families (50).

Atypical presentations are well-recognized, in particular facial sparing forms and infantile onset forms, with severe rapidly progressing disease observed in about 4% of cases from a UK cohort (46,51). These patients also show mild to moderate cognitive impairment and epilepsy and higher occurrence rate of hearing loss and retinopathy. Interestingly, homozygosity for FSHD does not appear to correlate with a more severe phenotype (49).

### 125.3.2 Genetics

FSHD is inherited as an autosomal dominant condition, although up to 10–30% of cases are sporadic or due to germ line mosaicism. The large majority of patients with FSHD (>95%) have a partially deleted D4Z4 repeat

array in the subtelomeric region of chromosome 4q35 (FSHD1). This repeat normally consists of 11–100 D4Z4 units, each 3.3 kb in size and ordered head to tail. Patients with FSHD1 have a partial and internal deletion of the repeat array leaving 1–10 units on one chromosome 4. An almost identical repeat array is also present in the chromosome 10q subtelomere, but contractions on this chromosome are nonpathogenic. Each D4Z4 unit has several transcripts, none of which is stable likely because of absence of polyadenylation signal in internal D4Z4 units. The major transcript in each D4Z4 unit is the *DUX4* gene, a retrogene encoding a double homeo-box protein.

About 3% of FSHD patients have no D4Z4 contractions (FSHD2) but show changes in the chromatin structure of D4Z4 similar to what is observed in FSHD1 patients. Clinically, patients with FSHD2 are indistinguishable from patients with FSHD1, although FSHD2 patients are more frequently sporadic cases and show no gender difference in terms of disease severity (52).

A correlation has been made between the size of the contraction and severity of the disease, in particular age at onset and rapidity of progression. Supporting this correlation is the finding of a more severe phenotype in patients with *de novo* changes, who usually show larger D4Z4 contractions.

### 125.3.3 Pathogenesis

To date, disease models have suggested that contraction of D4Z4 repeats causes chromatin remodeling and transcription deregulation of genes close to the D4Z4 units. Normally, D4Z4 repeats are in a relatively closed chromatin configuration. Repeat contraction causes partial loss of DNA methylation, which, together with loss of repressive histone modifications, opens the chromatin structure, potentially affecting transcript processing

(53,54). Upregulation of several genes located proximal to D4Z4 was reported in FSHD1 patients but has not been confirmed by subsequent studies. The 4q shows several different configurations (4qA and 4qB) and variants due to 4q polymorphisms, with a few specific sequence variants being casually related to FSHD1 (with the 4qA161 being the most common) (55,56).

It has been observed that at least one D4Z4 unit is required to develop FSHD, as monosomy of 4q does not lead to FSHD. Based on this observation, Lemmers and coworkers reasoned that the minimal pathogenic region might reside in the first or the last D4Z4 unit, which indeed has been shown to have a transcriptional profile different from what is observed for the internal units (56). Indeed, immediately distal to the last unit, there is a region called pLAM1 that has been shown to play a crucial role in the development of FSHD. The pLAM1 sequence contains a poly(A) signal that presumably stabilizes transcripts of the *DUX4* gene in the last D4Z4 unit. Patients with FSHD1 have been shown to have an identical sequence in the last D4Z4 unit and the immediately flanking pLAM1 sequence, and specific sequence variants unique to the permissive haplotypes confer pathogenicity to the repeat irrespective of its chromosomal localization (56). The distal pLAM1 sequence is preserved in FSHD1 patients, with deletion extending proximally to the D4Z4 repeat array, and also in FSHD2 patients, with a similar chromatin relaxation of a 4qA161 chromosome independent of D4Z4 repeat array contraction (56). This model by Lemmers and coworkers therefore suggests that two polymorphisms create a polyadenylation site for the distal *DUX4* transcript, located in the pLAM1 sequence, which, in combination with the chromatin relaxation of the repeat, leads to increased *DUX4* transcript levels. A toxic gain of function caused by the stabilized distal *DUX4* transcript could therefore give rise to the disease (Figure 125-8) (56).

**FIGURE 125-8** Schematic representation of a unifying mechanism for pathogenesis of facioscapulohumeral muscular dystrophy (FSHD). (A) Indicates the normal D4Z4 repeats (indicated with gray triangles) with closed chromatin configuration (solid line); (B1) In case of contraction of the D4Z4 repeats (FSHD1), the chromatin adopts a more open configuration (dotted line), leading to the expression of the *DUX4* mRNA as indicated in (C), that on permissive chromosomes is stabilized by the presence of the polyadenylation signal distal to the D4Z4 repeats. (B2) Rare patients may present no contraction of the D4Z4 repeats (FSHD2) but still show a more open configuration of the chromatin, leading to the expression of the *DUX4* mRNA as indicated in (C) in the case of FSHD1 patients.

### 125.3.4 Genetic Counseling

FSHD is inherited with autosomal dominant manner and most individuals (70–90%) with this condition have one parent showing some clinical symptoms of the condition. The rest of the cases are caused by a *de novo* event of mitotic origin or germ line mosaicism. In view of the extreme clinical variability of the condition and of reported somatic mosaicism that could affect recurrence risks (50), it is appropriate to offer appropriate clinical examination and genetic testing to parents in absence of positive family history.

If one of the parents is affected, the recurrence risk for the sibs of an affected individual is 50%, independent of sex. The incidence of germ line mosaicism is unknown, but recurrence risk in the case of absence of contraction in the parents is reported as low. Affected individuals have a reproductive risk of 50%. Following appropriate genetic counseling, molecular testing could be offered to asymptomatic at-risk family members aged above 18 years.

### 125.3.5 Genetic Diagnosis

Genetic confirmation of FSHD is currently performed by Southern blotting and hybridization of a set of probes able to establish the size of the D4Z4 repeat array and also to determine the genetic background of 4q35 (4qA or 4qB). Unaffected individuals have two 4q35 alleles of >40 kb on an EcoRI DNA digestion. Affected individuals will have one allele between 10–38 kb. Results of 40–50 kb are inconclusive. Long-range PCR and the newest molecular combing techniques have been recently developed to facilitate genetic diagnosis of FSHD (57). Diagnosis of FSHD2 is currently only made on a research basis, and there is no currently validated genetic test available for these patients.

### 125.3.6 Prenatal Testing

Prenatal testing is available in the case of at-risk pregnancies, given that the mutation of the affected parent is known. DNA of the fetus is extracted from cells obtained by sampling of chorionic villi at 12 weeks pregnancy or by amniocentesis (at 15–18 weeks of gestation). As conventional Southern blot is not suitable at the single-cell level, PGD cannot be offered at the moment. A PCR-based multiplex approach on single cells was developed to perform an indirect familial segregation study of pathogenic alleles; however, the relatively high recombination risk reduces the sensitivity of this technique in PGD (58).

### 125.3.7 Management and Treatment

To date, no disease-specific treatment for FSHD is available. Medical management includes physiotherapy, use of assistive devices and pain medication. Availability of

treatments of complications, such as hearing loss and retinopathy, justifies regular surveillance, in particular for patients with the early-onset forms. Respiratory and cardiac involvement should be monitored and managed accordingly. Scapular fixation has been shown to enhance arm mobility in patients with FSHD; however, no clear controlled studies are available.

Different pharmacological interventions, in particular corticosteroids and  $\beta$ -2 antagonists, have been tested, showing inconsistent but mainly ineffective results. A clinical trial testing the effect of myostatin block on muscle growth showed no benefits on muscle function or strength (59). Currently, other novel myostatin inhibitors are considered to have potential beneficial effect on FSHD as well as other muscular dystrophies but these remain to be tested in clinical trials.

## 125.4 EMERY–DREIFUSS MUSCULAR DYSTROPHIES AND OTHER CONTRACTURAL PHENOTYPES

### 125.4.1 Emery–Dreifuss Muscular Dystrophies

Emery–Dreifuss muscular dystrophies (EDMD) represent a clinically and genetically heterogeneous group of diseases. The clinical diagnosis of EDMD is based on the presence of (1) early contractures, in particular of elbow flexors, Achilles tendons, and spinal extensor muscles; (2) slowly progressive muscle wasting and weakness with scapulo–humero–peroneal distribution and (3) cardiac involvement, usually by the 3rd decade of life, in particular conduction defects and arrhythmias. CK levels are usually normal or moderately elevated (2–20 times the upper normal limit). Muscle histopathology shows non-specific myopathic or dystrophic findings.

EDMD is caused by mutations in three different genes. Two autosomally inherited forms are due to either dominant (AD-EDMD) or recessive (AR-EDMD) mutations in the *LMNA* gene (60), while mutations in the *EMD* and *FHL1* genes are responsible for the X-linked forms (X-EDMD) (61). AD-EDMD is the most common form, and it is often more severe than the *EMD* gene-related form. The AR and the *FHL1*-related forms are rare and reported so far only in a few patients. For the *FHL1* gene-related form, see paragraph “*FHL1* gene-related myopathy.” Nesprin mutations are also discussed later. An important differential diagnosis of a contractural phenotype is Bethlem myopathy, discussed in a separate paragraph.

The overall prevalence of EDMD is unknown. In the past, EDMD was estimated to be the third most common form of muscular dystrophy after DMD and BMD. In the northern English population, however, the X-linked form has a prevalence of 0.13/100,000, while combined prevalence of AD-EDMD and LGMD1B (also caused by *LMNA* gene mutation) is about 0.20/100,000 (2).

#### 125.4.1.1 Clinical Features.

**125.4.1.1.1 AD and X-EDMD.** AD-EDMD and X-EDMD show partly overlapping clinical phenotypes (Figure 125-9). AD-EDMD is characterized by early onset of muscle weakness with scapulo–humero–peroneal distribution that might precede joint contractures. Wasting of the upper arms and lower legs is common. In patients with X-EDMD, muscle involvement is usually preceded by joint contractures, and the muscle weakness and wasting shows a typical humeroperoneal distribution. In both conditions, the weakness is usually slowly progressive in the first decades, while in later stages, weakness spreads to the scapular and pelvic girdles. Loss of ambulation might also occur, in particular after the third decade in the AD-form, when the progression of the muscle wasting becomes more rapid. Interestingly, patients with *LMNA*-gene mutations, independent of the variety of clinically detectable skeletal muscle involvement, show the same pattern of leg muscle involvement on leg muscle imaging, in particular within the soleus and medial head of the gastrocnemius (62). Contractures usually involve elbows, ankles, cervical, and spinal muscles causing spinal rigidity. The progression is variable and not age-dependent. Severity of contractures of the

spine and lower limbs can greatly influence ambulation. Surgical release of Achilles tendon contractures as well as orthoses can improve ambulation.

Cardiac involvement usually arises by the 3rd decade, with palpitations, presyncope, syncope, poor exercise tolerance, and dyspnea being the first symptoms. Patients can show a wide range of cardiac involvements, such as supraventricular arrhythmias (atrial premature contractions, tachycardia or fibrillation, atypical atrial flutter and atrial paralysis), different degrees of atrio-ventricular block, ventricular arrhythmias (ventricular premature beats or unsustained ventricular tachycardia), nondilated, dilated, or restrictive cardiomyopathy, and sudden death that can occur despite pacemaker implantation (63,64). The risk of ventricular tachyarrhythmia and dilated cardiomyopathy with left ventricular dilatation and dysfunction is higher in AD-EDMD than in the X-linked form. Rather than the pacemaker, ICD implantation in patients with a *LMNA* mutation is more likely to be effective in treating possibly lethal tachyarrhythmias and should be considered in all EDMD patients with confirmed *LMNA* mutation (65). Patients can also develop respiratory impairment and cerebral emboli (64).

**FIGURE 125-9** Clinical images of patients with Emery–Dreifuss muscular dystrophy (EDMD). In the left panel, a patient with *LMNA* gene mutation (AD-EDMD). In the right panel, a patient with *EMD* gene mutation (X-EDMD).

Intrafamilial and interfamilial variability of phenotypes is common, in particular, in the AD-form, and incomplete penetrance or semidominant inheritance has also been reported (66,67). Female carriers of the X-linked form usually do not present muscle weakness but can be at risk of cardiac defects.

Different phenotypes of laminopathies (EDMD, LGMD1B or cardiomyopathy) have been observed in different members from the same family segregating the same mutation in the *LMNA* gene. More severe phenotypes have been observed in rare patients segregating mutations in both *EMD* and *DES* gene (68) or in *EMD* and *LMNA* (69), suggesting that digenism, in addition to environmental factors and modifier genes, may partially explain the extreme clinical variability observed in some rare EDMD families.

**125.4.1.1.2 AR-EDMD.** Autosomal recessive inheritance of EDMD has been described in a single patient (70). The patient was homozygote for the *LMNA* mutation C664T, causing the amino acid change in a conserved histidine in position 222 of the gene. The patient showed first symptoms at 14 months, with difficulties walking and then later difficulties standing because of contractures. At age 40, he showed severe and diffuse muscle wasting and was wheelchair bound. He did not show any cardiac involvement. Heterozygous parents were unaffected.

#### 125.4.1.2 Genetics.

**125.4.1.2.1 *LMNA* Gene.** Mutations in the *LMNA* gene are responsible for the AD as well as for the rare AR-EDMD form. The *LMNA* gene, located in 1q21.3, contains 12 exons and by alternative splicing encodes the two A-type lamins, Lamin A and Lamin C. In addition to EDMD, mutations in the *LMNA* gene are responsible for a wide and heterogeneous group of disorders called “laminopathies” and also responsible, in addition to the neuromuscular disorders affecting the striated muscles (AD-/AR-EDMD, LGMD1B, *LMNA*-related congenital muscular dystrophy and dilated cardiomyopathy with conduction system defects), for disorders of the peripheral nerve or fatty tissue, as well as disorders involving multiple tissues such as mandibuloacral dysplasia, Hutchinson–Gilford progeria (HGPS), atypical Werner syndrome, etc. (71). A strict genotype–phenotype correlation has not been yet identified, although HGPS tends to correlate with C-terminal splicing defects, while other conditions present specific mutation hot spots (72). EDMD-associated mutations are distributed throughout the gene although a few mutations recur (72,73). Marked clinical heterogeneity is observed even between patients with the same mutation, and some mutations appear to be partially penetrant.

Mutations in the *LMNA* gene are detected by direct sequencing in about 45% of cases of AD-EDMD (66). The majority of mutations are missense (>80%), but nonsense mutations as well as small deletions/insertion can also occur. The UMD-*LMNA* mutation database

included, to date, more than 400 mutations for all known laminopathies, and about 46% of these changes were detected in EDMD patients only (UMD-*LMNA* database at [www.umd.be/LMNA](http://www.umd.be/LMNA)). Large deletions/duplications of the *LMNA* gene have not yet been reported in patients with EDMD. Missense changes give rise to normal-size mutant proteins, and Western blot analysis of patients demonstrate normal levels of the protein. Conversely, nonsense mutations cause haploinsufficiency with 50% of normal protein expression (74).

Lamins A (72 kDa) and C (67 kDa) are type V intermediate filament proteins with a common nonhelical N-terminal domain, a central  $\alpha$ -helical coiled-coil rod domain, and a unique C-terminal tail domain. Lamins A, B, and C are the major components of the nuclear lamina, a proteinaceous meshwork underlying the inner nuclear membrane that provides a structural framework for the nuclear envelope and offer an anchoring site at the nuclear periphery for interphase chromosomes. Nuclear lamins also interact with integral proteins of the inner nuclear membrane and proteins of nuclear pore complexes, coordinating nuclear architecture, DNA synthesis, chromatin organization, gene transcription, cell cycle progression, cell differentiation, migration, and response to DNA damage.

**125.4.1.2.2 *EMD* Gene.** X-EDMD is mostly caused by mutations in the *EMD* gene, located in Xq28, encoding emerin, a small integral membrane protein that is located in the inner nuclear membrane and a member of the LEM domain proteins (75). Mutations in *EMD* also cause a rare form of X-linked LGMD (76,77) and an X-linked isolated cardiac disease with prominent sinus node disease and atrial fibrillation (69).

*EMD* has six exons, and sequencing analysis is able to detect almost 100% of mutations in patients, with established X-EDMD with no emerin on immunohistochemistry, that correspond to about 61% of all cases of X-EDMD (61). To date, the UMD database for *EMD* genes lists more than 96 different mutations spread throughout the gene with no mutation hot spots (UMD-*EMD* database at [www.umd.be/EMD](http://www.umd.be/EMD)).

Emerin is a 34-kDa protein with a hydrophobic C-terminus anchored in the nuclear membrane and an N-terminal tail projecting into the nucleoplasm. The majority of the mutations (95%) are null mutations, giving rise to absence of emerin on immunostaining of emerin at the nuclear membrane. A few missense or in-frame mutations result in aberrant targeting at the inner nuclear membrane and binding to lamins.

**125.4.1.3 Pathogenesis.** Emerin and Lamin A/C are thought to have a close functional relationship, and direct interaction between these proteins has been demonstrated (78). Currently, it is believed that two mechanisms could be involved in EDMD pathogenesis: (1) structural mechanisms caused by mechanical stress in skeletal and cardiac muscle, and (2) modification of gene expression relative to abnormal chromatin organization

associated with alteration of proliferation/differentiation of muscle cells (60,71,73). The basis of the extreme clinical variability observed in EDMD is still unclear. It has been shown that patients with frameshift *LMNA* mutations present with a late-onset phenotype caused by a loss-of-function mechanism secondary to haploinsufficiency, while dominant-negative or toxic gain-of-function of the protein may cause a more severe phenotype with early onset (79). The occurrence of extreme phenotypes associated with mutations in the same codon suggests the presence of genetic modifiers. Supporting this theory is the observation of patients with digenism (68). In particular, the occurrence of independent mutations in related interacting proteins (such as emerin and Lamin A/C) may synergistically contribute to disease severity of EDMD.

**125.4.1.4 Genetic Analysis and Counseling.** According to the mode of inheritance, testing of the different genes should be performed. In the case of sporadic male patients, emerin (and if available FHL1) immunoanalysis can help to distinguish if it is an X-linked or AD-form. Affected females are more likely to have the AD-form, prompting *LMNA* gene testing. Carrier testing of at risk relatives for the AR- and X-linked forms, as well as pre-natal, and PGD for at risk pregnancies requires prior identification of the mutations in the affected individual.

## 125.4.2 *SYNE1*- and *SYNE2*-Related EDMD-Like Myopathies

Mutations in the *SYNE1* and *SYNE2* genes, encoding nesprin 1 and 2 proteins, have been described in a few patients affected by myopathies with cardiac involvement and muscle involvement—overall reminiscent of EDMD but not totally typical of the EDMD phenotype (80). Nesprins are spectrin-repeat proteins that bind both emerin and lamins A/C and link the nucleoskeleton to the inner and outer nuclear membranes, membranous organelles, the sarcomere, and the actin cytoskeleton. Indeed, fibroblasts of patients with mutations in the *SYNE1* and *SYNE2* genes exhibited nuclear morphology defects and specific patterns of emerin mislocalization. Interestingly, a homozygous splice-site mutation of the *SYNE1* gene has also been reported in an autosomal recessive form of congenital muscular dystrophy segregating in a consanguineous Palestinian family (81). The phenotype was characterized by bilateral clubfoot, decreased fetal movements, hypotonia, delayed motor milestones, and progressive motor decline.

## 125.4.3 *FHL1* Gene-Related Myopathy

*FHL1*-related myopathies represent a recently recognized heterogeneous group of disorders, with X-linked myopathy with postural muscle atrophy and generalized hypertrophy (XMPMA) (82), and X-linked dominant scapuloperoneal myopathy (X-SM), being the first

associated with *FHL1* gene mutations (83). Subsequently, *FHL1* gene mutations were identified in a wide spectrum of partly overlapping conditions such as reducing body myopathy (RBM) (84), rigid spine syndrome (RSS) (85), EDMD (61), and in a single family with contractures, rigid spine, and cardiomyopathy (86). *FHL1*-related myopathies share some clinicopathological features with EDMD, such as the scapuloperoneal involvement, the asymmetric muscle involvement, and the rigid spine, but they differ for age at onset, distribution and severity of muscle weakness, progression rate, cardiac and respiratory involvement, and presence or absence of reducing bodies (RB) on Menadione- nitroblue tetrazolium (NBT) staining. *FHL1*-related disorders could be divided into two main subgroups, the “RB subgroup” including RBM, X-SM, and RSS, all characterized by RB at histological examination, and a second subgroup, including the XMPMA and EDMD, with later onset and absence of RB (61).

The human *four-and-a-half LIM domain 1* (*FHL1*) gene, located on Xq26.3, is a 32-kDa protein with four-and-a-half tandem repeat LIM domains cysteine-rich, tandem zinc finger protein interaction motifs first recognized in the Lin-11, Isl-1, and Mac-3 homeodomain transcription factors (87). LIM domain proteins are involved in the skeletal and cardiac structure and function (88,89). *FHL1* has at least three isoforms (*FHL1A*, *B*, and *C*) with different primary structures, expression patterns, binding partners, and subcellular localizations (90). All isoforms are highly expressed in skeletal muscle and to a lesser extent in heart, but *FHL1A* is the prevalent muscle isoform (91). *FHL1* localizes to the sarcomere and the sarcolemma and participates in muscle growth, differentiation and sarcomere assembly (92).

**125.4.3.1 Reducing Body Myopathy.** RBM is a rare and severe condition characterized by early age of onset (usually infancy or childhood), progressive proximal muscle weakness, and spinal rigidity, with rapid progression into respiratory failure and death. In cases of adult onset (third to fourth decade), cardiac involvement is also observed. Both sexes can be affected, but onset is usually earlier in males (average 5 years in males versus 7 years in females). CK levels can be found increased up to 10 times the normal levels, with usually higher increase in males than females (92).

RBM is histologically characterized by the presence of intracytoplasmic inclusions of RB in the muscle fibers. Because of their high sulphhydryl content, RBs reduce NBT and therefore strongly stain with menadione-NBT in the absence of the substrate  $\alpha$ -glycerophosphate (93). The *FHL1* protein has been shown to be a major component of RB (84). *FHL1* gene analysis in 16 unrelated RBM families led to the identification of 10 missense mutations and one in-frame deletion (84,92,94). All variants so far identified localize in the second LIM domain and mainly affect zinc-coordinating cysteine and histidine residues, leading to instability of the domain and protein

misfolding. A more severe phenotype is observed in association with mutations at residue 123 (92).

**125.4.3.2 Rigid Spine Syndrome.** Rigid spine is a common feature in FHL1-related myopathies, in particular in RBM, X-SPM, XMPMA, and EDMD. Interestingly, a unique *FHL1* gene mutation was identified in a single patient presenting with RSS and later muscle atrophy (85). Muscle analysis identified RB, suggesting that this case could indeed represent a milder form of RBM. To corroborate this hypothesis, the mutation identified in this patient (p.151-153delVTC) affects a cysteine residue in the second LIM domain, as for the RBM cases.

**125.4.3.3 X-linked Scapuloperoneal Myopathy.** X-SPM is characterized by proximal upper limb weakness with adult onset (second or third decade), scapular winging, early foot drop, rigid spine, and late contractures (83). Cardiac involvement has also been observed, while respiratory involvement appears uncommon. Men are usually more severely affected and may become wheelchair bound. RBs have been observed on muscle biopsy analysis with menadione-NBT analysis, and together with the observed clinical overlap with adult-onset RBM, it suggests that X-SPM and RBM could represent extremes of a unique clinical continuum. Two *FHL1* gene mutations, affecting residue tryptophan 122, have been described in the two unrelated families so far reported (83,95). Molecular dynamics simulation of the W122C mutation revealed no major distortions of the protein structure or disruption of zinc binding. An increase in the nonpolar, solvent-accessible surface area has been observed in one or both of two clusters of residues, suggesting that the mutant proteins have a variably increased propensity to aggregate (95).

**125.4.3.4 X-linked Myopathy with Postural Muscle Atrophy and Generalized Hypertrophy.** XMPMA is characterized, as indicated by the name, by late-onset postural muscle atrophy associated with generalized muscle hypertrophy (82). Onset is in the third decade, and patients show a typical pseudoathletic appearance, associated with moderate scapulo-axio-peroneal weakness, atrophy of postural muscles, and bent spine. Cardiac and respiratory failure is also observed and may be the cause of death. CK levels are normal or increased up to 10 times the normal levels. So far, *FHL1* mutations have been described in 7 families with XMPMA (82,96). Two missense mutations affect conserved cysteine or histidine residues in the fourth LIM domain (C224W and H246Y) (82,96). The third known missense change in exon 7 only affects isoform FHL1B, indicating that this also plays an important role in skeletal muscle function (V280M). Another *FHL1* mutation (127-I-128) results in the insertion of an isoleucine in the linker region between the two zinc fingers of the second LIM domain (82,97). This two-amino acid linker (C-X2-C) is typically invariant in length, and the insertion of a large aliphatic hydrophobic isoleucine between the

rigid aromatic phenylalanine-127 and the hydrophilic threonine-128 is supposed to alter the orientation and the spatial relationship between the tandem zinc fingers (98). This mutation has been identified in three apparently unrelated British families, with a broad phenotypic spectrum within members of the same families as well as between families. Females were variably but more mildly affected. Haplotype analysis of the *FHL1* region revealed that the families share a common haplotype suggesting a British founder effect (97). Finally, a splice site mutation in intron 4 (c.688+1G>A) has been detected in another family, leading to splicing from exon 5 to exon 8 and the expression of a C-terminal truncated protein identical to isoform FHL1C (96).

**125.4.3.5 Emery–Dreifuss Muscular Dystrophy.** *FHL1* gene mutations have been so far reported in seven families segregating X-EDMD (61). At onset, the phenotype is characterized by a myopathy with scapuloperoneal and/or axial distribution and joint contractures, with age at onset ranging from childhood to the fifth decade. All patients showed pelvic, peroneal or pelvi-peroneal weakness, with associated upper limb (mainly scapular) involvement in most of them. Additional axial and facial involvements were also observed. Limb joint (ankles, elbows, hips, knees, and rarely wrists, fingers, and shoulders) contractures, neck stiffness, and rigid spine were also common features. Patients invariably also showed cardiac involvement (conduction defects, arrhythmias, and hypertrophic cardiomyopathy) with onset ranging from early teens to adulthood, with symptoms of supraventricular or ventricular arrhythmias. Heterozygous female carriers were either asymptomatic or had cardiac disease and/or mild myopathy. Interestingly, four male relatives with *FHL1* gene mutation presented isolated cardiac disease, and an overt hypertrophic cardiomyopathy was present in two. CK levels were normal or moderately elevated. The *FHL1* mutations responsible for the EDMD phenotype are located in the most distal exons (exons 5–8), affecting all three FHL1 isoforms. One of these EDMD-causing mutations (C209R) has also been reported in a German family with male patients affected by hypertrophic cardiomyopathy and rigid spine, but no myopathy (86).

**125.4.3.6 Genetics and Pathogenesis.** More than 25 *FHL1* mutations have been reported to date, the majority of which affecting the second LIM domain. Mutations affecting the critical zinc-binding residues, such as in RBM patients, appear to affect the protein folding and structure. All LIM2 domain mutations disrupt tandem zinc-finger topology and the interface required for protein–protein interaction (87). Modeling studies have shown that the mutations do not cause protein misfolding per se, but the protein aggregation may be caused by the exposure of nonpolar surfaces (95). Aggregates increase over time in RBM, suggesting that toxic accumulation of protein aggregates might be responsible for the disease. Mutations observed in XMPMA and EDMD

patients do not give rise to RB, although desmin-positive aggregates are observed in the muscle from these patients (82). It has been hypothesized that this second group of mutations causes loss of normal protein function by reducing FHL1 protein expression and/or impairing protein partner binding. The milder phenotype associated in association with mutations affecting the most distal part of the gene is also due to the different effect of the mutations on the three FHL1 isoforms (98).

FHL1 plays an important role in the heart, connecting the muscle stretch sensor machinery interacting with titin and the downstream hypertrophic response, such as the members of the MAPK signaling pathway (99–101). Indeed, FHL1 knockout mice show reduced hypertrophy-dependent activation of ERK2, one of the members of MAPK pathway (99). It has also been shown that FHL1 has a role in the regulation of the functional expression of KCNA5, a component of the voltage-gated K<sup>+</sup> channel (Kv1.5), a fundamental protein in atrium repolarization, which also represents a therapeutic target in the treatment of atrial fibrillation (101–103).

**125.4.3.7 Genetic Counseling.** FHL1-myopathy is an X-linked condition differently affecting the two sexes, with variable mode of inheritance (recessive or dominant) according to the specific mutation. Females can be completely asymptomatic or show a variable degree of symptoms, ranging from a mild phenotype, with later onset, to the more severe early-onset RBM phenotype (92,97). Carrier testing of at-risk relative and eventual prenatal testing requires prior identification of the mutation in the affected subject.

## 125.4.4 Bethlem Myopathy

Bethlem myopathy (BM), allelic to the more severe form of Ullrich congenital muscular dystrophy (CMD) (see Section 125.7) is an important differential diagnosis for EDMD. The extracellular matrix protein collagen VI (ColVI) is composed of three chains,  $\alpha 1$ ,  $\alpha 2$ , and  $\alpha 3$  that assemble in tetramers to form a microfibrillar network in many tissues, including skeletal muscle. The three ColVI peptides associate into collagen VI triple helical monomers, followed by assembly into disulfide bonded dimers that then align laterally to form tetramers, the secreted form of collagen VI, which associate end to end outside the cell to form the characteristic microfibrils. Despite its ubiquitous expression pattern, effects of collagen VI mutations in human or mouse show strikingly muscle specific phenotypes. Indeed, Collagen VI chains are encoded by the *COL 6A1*, -2 and -3 genes, and mutations in these genes cause ColVI myopathies, including Ullrich CMD, BM, and other intermediate phenotypes, constituting a continuous clinical spectrum. Because collagen VI is thought to play a role in mediating tissue morphogenesis as well as playing a potential role in cell cycle signaling and tissue homeostasis, it is possible that mutated collagen

VI leads to myopathy by disruption of one or both of these roles.

Classic BM is characterized by the combination of a relatively mild proximal myopathy and variable contractures. Ullrich CMD is the most severe end of the spectrum, presenting early in life with hypotonia, muscle weakness, motor delay, proximal contractures, and distal hyperlaxity (for more details see “Congenital muscular dystrophies”). Other phenotypes included in the spectrum are severe early onset forms of BM, milder forms of Ullrich CMD, or intermediate forms not classified as BM or Ullrich CMD (104). Moreover, rare forms of LGMDs (105) and a rare form of autosomal recessive myosclerosis myopathy (106) are also included in this group of diseases. Inheritance of BM was classically described as autosomal dominant, however, recent reports have shown different inheritance patterns, further increasing the clinical and genetic complexities of this disease. Prevalence of BM is low, with estimated point prevalence in northern England of 0.77/100.000 live births, respectively (2).

**125.4.4.1 Clinical Features.** BM may present at any age, and indeed, it may be recognizable from birth with affected children presenting sometimes with torticollis and contractures. Prenatal onset of muscle weakness has been suggested in some families with diminished fetal movements, and affected infants are often hypotonic with delayed motor milestones. Proximal muscle weakness from childhood onward tends to be only slowly progressive, and there may be long periods of time when the condition does not progress at all. Other patients may be asymptomatic in childhood and present with mild muscle weakness and contractures in adult life. Considerable disability may be seen in some patients in late adult life, with more than two-thirds of patients older than 50 years requiring aids for ambulation outdoors, and some with respiratory failure secondary to diaphragmatic paralysis. A hallmark of this condition is the development of contractures, especially of the fingers, wrists, elbows, and ankles, and these, in addition to weakness, contribute to disability. The contractures can be dynamic in nature during childhood, and hypermobility of distal interphalangeal joints can be present together with long finger flexion contractures. Skin features typically seen in connective tissue disorders, such as keloid formation and “cigarette paper” scarring, as well as follicular hyperkeratosis, can also be present in patients with BM. Clinically, the condition may show overlap with autosomal dominant forms of LGMD (105) because of the proximal muscle weakness, especially as the full spectrum of the disease may not be seen in every patient. The presence of the contractures may cause confusion with EDMD, particularly if a rigid spine is present. In BM, there is no evidence of any cardiac involvement.

**125.4.4.2 Diagnosis.** Clinical diagnosis of BM is suggested by the presence of proximal muscle weakness associated with variable contractures, and unusual skin

features. CK levels are normal or mildly elevated. Muscle biopsy shows myopathic or dystrophic changes. In contrast to Ulrich CMD, collagen VI immunolabeling of muscle is often normal. Immunofluorescent (IF) labeling of collagen VI in fibroblast cultures is useful to guide molecular genetic testing of BM in a cost-effective and timesaving manner. Indeed, fibroblast IF technique is highly predictive of the presence of a *COL6A* mutation, with a positive predictive value of 75%, a sensitivity and negative predictive value of 100%, and a specificity of 63% (107). Muscle MRI is an additional tool in guiding molecular diagnosis of BM and often requested prior to performing molecular analysis. *Vasti* muscles are the most frequently and markedly affected muscles in the thigh. A rim of abnormal signal at the periphery of each muscle, with relative sparing of the central part, is also observed. Characteristic is the peculiar involvement of the rectus femoris, with a central area of abnormal signal within the muscle (108). BM patient also shows a rim of abnormal signal at the periphery of soleus and gastrocnemii.

Confirmation of a diagnosis of BM relies on the detection of a mutation in one of the three collagen genes, *COL6A1*, -2, and -3. These genes have 107 coding exons and frequent polymorphisms, thus mutation analysis is not straightforward. Sequence analysis allows detection of *COL6A* gene mutation in 60% of classical or unusually severe BM phenotypes (109). The most common pathogenic mechanism is represented by single amino acid substitutions disrupting the Gly-Xaa-Yaa motif of the highly conserved triple helical domain of one of the *COL6A* genes, followed by splice-site mutations, in particular of exon 14 in *COL6A1*, causing small in-frame deletions or insertions or frameshifting and nonsense mRNA decay.

Severity of the phenotype depends on the ability of mutant chains to be incorporated in the multimeric structure of collagen VI (110). The majority of mutations causing BM are usually heterozygous, dominantly acting mutations, resulting in either haploinsufficiency or with a dominant negative effect, affecting secretion and deposition of structurally abnormal collagen VI or compromising its interactions in the extracellular matrix of muscle (109,111). Recently, recessive inheritance of BM was reported in homozygous or compound heterozygous patients with a functional null mutation and a missense *COL6A* mutation (112,113).

Genetic heterogeneity within BM was suggested by exclusion by linkage and/or direct sequencing of the *COL6* loci in patients with a typical BM phenotype, suggesting that mutations in other genes may underlie at least some of these cases (Hicks et al, unpublished data).

**125.4.4.3 Genetic Counseling.** Recurrence risk for siblings in BM due to heterozygous mutations will depend on the affected status of the parents, requiring careful examination and molecular genetic testing of parents. In case of confirmed *de novo* mutations, recurrence risk will be low and will relate to the possibility of gonadal

mosaicism. In case of recessive mutations, recurrence risk for siblings will be 25%.

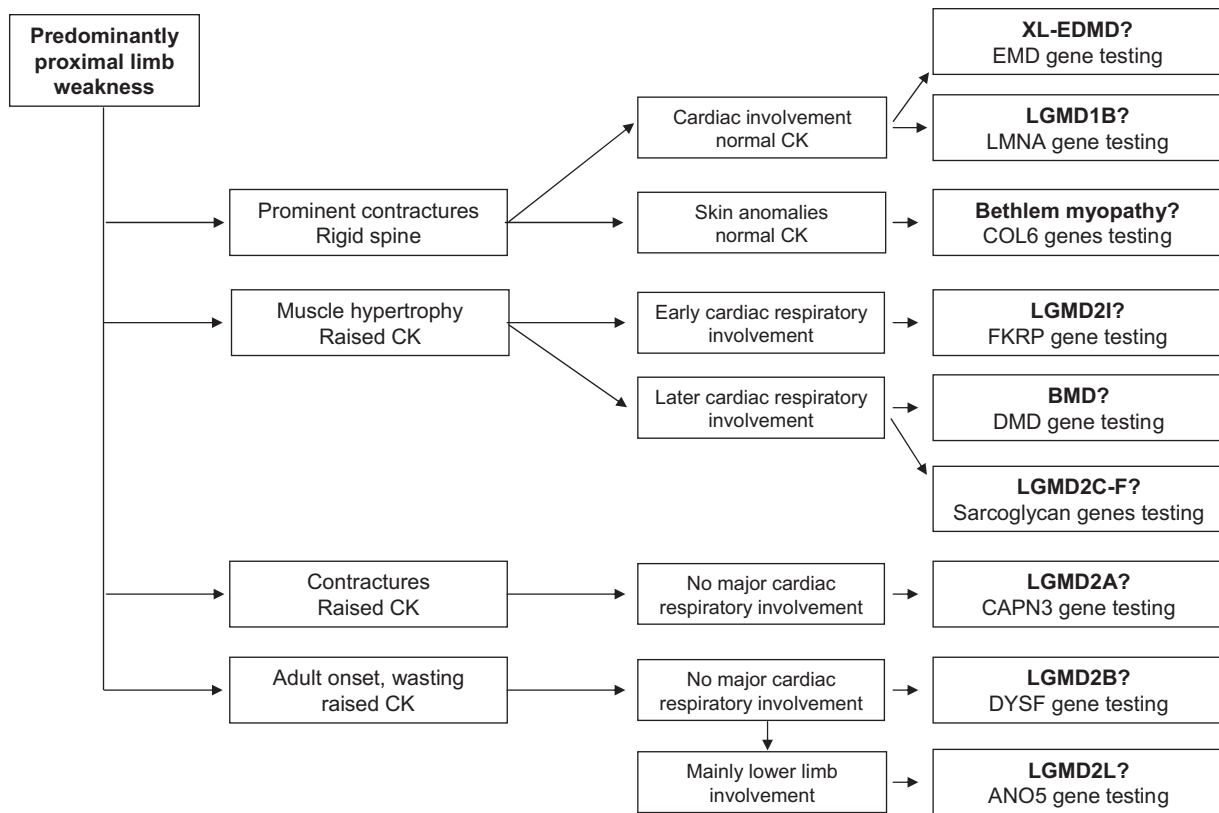

## 125.5 LIMB-GIRDLE MUSCULAR DYSTROPHIES

A highly genetically heterogeneous group of muscular dystrophies can be recognized as sharing the features of predominant involvement of the proximal musculature. This group is known as the LGMDs and is an area where great progress in diagnostic investigations has been made (114–116). The ability now to achieve a precise gene or protein-based diagnosis in many patients in this category means that the correct disease designation should include an indication of the molecular pathology whenever possible. Equally, the ability to distinguish the various subgroups within the LGMD category means that there is increasing knowledge about the various phenotypes seen in association with the genetically defined subtypes. The increasing awareness of the complications accompanying the various subtypes of LGMD is also crucial in management of patients and improving quality of life and longevity. Therefore, careful clinical characterization still has to take its place alongside the molecular diagnostic tools of gene and protein analysis.

In a patient presenting with suspected LGMD, mode of presentation and in particular the specific pattern of muscle involvement, additional clinical features, CK levels, and family history are key handles to reach a precise diagnosis (Figure 125-10). It is important to keep in mind that LGMDs are singularly rare and more common, and more likely diagnoses should be considered first, in particular dystrophinopathies. Muscle analysis is helpful in about 2/3 of the cases, but mutation analysis is the gold standard for reaching diagnosis. Currently, with appropriate testing, it is possible to reach a diagnosis in about 75% of cases of LGMD, but multidisciplinary approach for diagnosis is better achieved in specialized centers and is helpful for management, in particular, of cardiac and respiratory complications. Diagnostic precision is also pivotal for future genetic therapies.

### 125.5.1 Autosomal-Dominant LGMDs

Only a relatively small proportion of LGMD (possibly around 10%) show autosomal dominant inheritance (AD-LGMD) (114–116). The 2010 Gene Table lists eight genetic types of AD-LGMDs, including a number of disorders with clinically significant cardiac involvement (1). An important distinguishing feature in some of these disorders compared with autosomal recessive LGMD (AR-LGMD) is the lower CK, which may be in the normal range or elevated only 3–5 times. Individually, many of the AD-LGMDs are relatively rare and restricted to specific family or population groups, with the important exception of the *LMNA* gene-related form. Most of the AD forms of LGMD are caused by mutations in genes,

**FIGURE 125-10** Flow chart for diagnostic approach in case of a patient with suspicion of limb girdle muscular dystrophy.

which are also associated with other phenotypes. In assessing a family with possible LGMD and dominant history, important differential diagnoses are FSHD and BM. Facial muscle involvement in individual patients with FSHD may be relatively mild, and this diagnosis could be easily checked by DNA analysis.

**125.5.1.1 LGMD1A.** LGMD1A is a rare disease, first described in a large north American pedigree with a predominantly proximal muscular dystrophy associated in some cases with dysarthria and tight Achilles tendons. Linkage to chromosome 5q led to identification of mutations in the myotilin (*MYOT*) gene, which encodes a component of the muscle sarcomere (117). No patients had arm weakness without leg weakness, and distal weakness was a late feature. Age at onset ranged from 18 to 35 years, with some suggestion of anticipation. Progression of the disease was very slow, with very few patients confined to a wheelchair. CK values were usually only mildly elevated. *MYOT* mutations more commonly cause myofibrillar myopathy (MFM) (118). Following the first description of LGMD1A, further families segregating *MYOT* gene mutation have been described, giving rise to a clear-cut LGMD phenotype different from MFM. A novel *MYOT* mutation was recently reported in a LGMD1A family with patients presenting with a late onset and rapidly progressing weakness, leading to loss of ambulation and respiratory failure (119). The onset of weakness in proximal muscles and muscle MRI findings were clearly different

from those observed in MFM patients, and myofibrillar pathology was limited. Although cardiac and respiratory complications are less common in patients with *MYOT* mutation compared with other genetic forms of MFMs, a high level of suspicion for these complications is always necessary in patients with LGMD1A. The *MYOT* mutations described in LGMD1A families (R6H, S55F, T57I, and R405K) are localized in different exons of the protein, indicating no genotype–phenotype correlations.

**125.5.1.2 LGMD1B.** Autosomal dominant LGMD is one of the various clinical presentations observed in patients with mutations in the *LMNA* gene. Of all the disorders classified within the AD-LGMD group, laminopathy in its various manifestations would appear to be numerically the most significant, to date.

LGMD1B presents with a predominantly proximal muscular dystrophy with minimal or late contractures and a tendency to atrioventricular conduction defects that increased with age. Indeed, when there is skeletal muscle involvement with laminopathy, there is also a very high risk of cardiac disease, in particular, progressive atrial arrhythmias with a subsequent risk of cardiomyopathy and ventricular arrhythmias. Even with pacing, there is a high risk of sudden death and consideration of the use of implantable defibrillators in the presence of cardiac involvement is recommended (120).

The essentially invariable cardiac involvement in the muscle-related laminopathy phenotypes make imperative to make a clear diagnosis. Moreover, given the variety

of presentations, potentially not yet fully elucidated, genetic diagnosis of laminopathy should be considered in any families with muscular dystrophy with a dominant family history, especially if there is a history of cardiac disease or sudden death. Diagnosis relies upon the demonstration of a *LMNA* gene mutation, because the protein is not altered in muscle biopsy samples. The ability to study the *LMNA* gene directly has also revealed the presence of a large number of *de novo* mutations and a significant level of germ line mosaicism. Because of the high rate of new mutations in this condition, the diagnosis should be considered in other cases of muscular dystrophy without a clear cause from examination of the muscle biopsy.

The majority of reported LGMD1B mutations are confined to the first 10 exons of the gene, with rare patients with mutation in exon 11 showing remarkable clinical variability, with specific features not reported in other LGMD1B patients (121). In particular, one patient had congenital weakness and died in early childhood. In two other patients, severe cardiac problems arose early, and in one of these, cardiac signs preceded the onset of skeletal muscle weakness by many years. The fourth case had a mild and late-onset LGMD1B phenotype. A lethal phenotype has been observed in association with a homozygous *LMNA* nonsense mutation (Y259X), where, in the heterozygous state, the mutation caused a classic LGMD1B phenotype in the same family (122).

Among the myriad of diseases caused by mutations in the *LMNA* gene, as well as AD-EDMD (see Section 125.4), congenital muscle diseases have also been reported (for more details, see Section 125.7).

**125.5.1.3 LGMD1C.** LGMD1C is caused by mutation in the Caveolin 3 (*CAV3*) gene, a muscle-specific component of the caveolin membrane, which is probably involved in signal transduction. Caveolin 3 localizes to the sarcolemma, coinciding with the distribution of dystrophin, with which it can also be shown to associate by immunoprecipitation, although it is not believed to be an integral part of the dystrophin complex. Caveolin 3 also associates with dysferlin. In addition to LGMD1C, *CAV3* mutations are also responsible for a variety of phenotypes including a distal phenotype, rippling muscle disease, myalgia, cardiomyopathy, and hyperCKaemia (123,124). Phenotypes might evolve over time, and the diseases can show different manifestations at different ages. Moreover, the same mutation in the *CAV3* gene may cause different presentations in members of the same family.

Patients with *CAV3* mutations may show very good muscle power and athletic ability. The most common symptom and reason for referral is myalgia, but patients can also present with cramps or distal and proximal muscle weakness. Rippling can be detected in childhood, and it is more frequently observed than weakness. Rippling and percussion-induced repetitive contractions should therefore be looked for in suspected cases, because they

may be easy to miss. Indeed, patients may be unaware that these phenomena are related to any muscle problem. Myoglobinuria as well as hypoglycemia can also occur (125). Progression of the disease is usually gradual, but relatively few patients with *CAV3* mutations had long-term follow-up (125). Cardiac and respiratory involvement is usually not observed. LGMD1C is the exception to the general rule that patients with AD disease generally have a lower level of serum CK, because here CK levels may be very high (10 times the upper limit of normal), and indeed, caveolinopathy may present only as hyperCKaemia. Rare homozygous cases have a more severe phenotype (126). LGMD1C is a rare form of LGMD. Frequency in Italian LGMD population is about 1%, while it has not been reported in northern England (2,127,128).

Diagnosis of LGMD1C may be suggested by the finding of reduced or absent caveolin 3 labeling in muscle, and it may be confirmed by mutation analysis (Figure 125-4) (127). Differential diagnosis should include autoimmune-mediated rippling muscle disease, where a mosaic pattern of caveolin loss is observed on muscle biopsy in absence of *CAV3* gene mutations.

A subgroup of patients presenting with muscular hypertrophy, muscle mounding, mild metabolic complications, and raised CK levels, and muscle biopsies with reduction of caveolae structure (129), have been shown to have homozygous mutations in another gene, called polymerase I and transcript release factor (*PTRF*; or cavin) involved in formation of caveole and stabilization of caveolins. In addition to the muscular dystrophy and lipodystrophy described in these patients, cardiac abnormalities leading to sudden death (long-QT syndrome, bradycardia, supraventricular and ventricular tachycardias) as well as smooth-muscle hypertrophy, leading to impaired gastrointestinal motility and hypertrophic pyloric stenosis, were also reported (130).

**125.5.1.4 Other AD-LGMDs.** Other forms of AD-LGMDs, defined only by their genetic localization in single families, have no known genetic cause, to date (1). Careful examination of these families and exclusion of known genes are pivotal. As cardiac and respiratory involvement is typical for dominant LGMDs, screening of these genetically unknown families is appropriate.

Following the identification of the locus for LGMD1D on chromosome 7q36 in two families, this rare form of AD-LGMD has also been described in several Finnish families (131), and mutations in the *DNAJB6* genes have recently been identified in a few of these and other families with different geographic origins (132,133). The phenotype is characterized by slowly progressive distal and proximal weakness, normal or mildly raised CK values but no major cardiac or respiratory involvement. *DNAJB6* is a member of the HSP40/DNAJ molecular cochaperone family with role in protein aggregation, and indeed affected muscles showed abnormal

protein aggregation and rimmed vacuoles, similar to what observed in MFM.

LGMD1E has a locus on 6q23, and it was reported in a single large family with affected subject presenting with proximal muscle weakness, dilated cardiomyopathy, and cardiac conduction abnormalities. Men were more severely affected than women for both skeletal and cardiac muscle manifestations of the disease. Progression of muscle symptoms was slow, and CK levels were raised to 1½–3 times the normal levels. Conduction disturbances preceded congestive heart failure in cases under follow-up, while sudden death was reported in other family members.

Few clinical details are yet known for LGMD1F (7q32), LGMD1G (4p21), and LGMD1H (3p23–p25) (134–136).

## 125.5.2 Autosomal Recessive Limb-Girdle Muscular Dystrophies

The autosomal recessive forms of LGMD (AR-LGMD) are more frequent than the dominant forms. Population-based studies show variation in frequencies of the different forms in different countries, reflecting the different gene frequencies in these population groups. LGMD2I is common in northern Europe, with a particularly frequent mutation (137–139), whereas in southern Europe, LGMD2A appears to be more prevalent (140).

**125.5.2.1 LGMD2A or calpainopathy.** LGMD2A has a fairly consistent and characteristic clinical

presentation (141–144). The weakness is typically proximal and affecting the posterior muscles of the lower limbs, associated with shoulder girdle involvement leading to scapular winging (Figure 125-11). The disease is predominantly symmetrical and atrophic, with prominent calves seen only in a minority of cases. Achilles tendon contractures may be an early sign, and contractures elsewhere, including of the spine and elbows, may also be prominent (141–143).

A large study by Saenz et al. showed a mean age at onset of <14 years, with first symptoms between 6 and 18 years of age in 71% of patients, with rare cases with onset in early childhood or adulthood (144). Pelvic girdle weakness is present and symptomatic from the onset, together with marked posterior thigh weakness and wasting, but often with very striking sparing of the hip abductors, even relatively late in the course of the disease. These features, combined with laxity of the abdominal muscles, lead to the development of a particularly characteristic stance in these patients (143). Scapular winging is usually present from the early stages, although it may be asymptomatic. A small minority of patients present muscle pain and can be misdiagnosed as polymyositis or metabolic myopathy; others are reported with hyperkalemia. Respiratory, and more frequently, cardiac function is usually preserved, and therefore a normal lifespan is expected. The disease shows high intrafamilial and interfamilial variability, in particular with regard to age at onset and rate of progression (145). Wheelchair dependency is typically observed after 10–20 years of

**FIGURE 125-11** Clinical images of patients with limb-girdle muscular dystrophy. In panel (A) LGMD2D; (B), (C), and (D) LGMD2A; (E) LGMD2I; (F) LGMD2D; (G) LGMD2L; (H) LGMD2D; (I) LGMD2L.

disease progression, with a mean age of 32.2 years (144). CK values are usually 10 times over the upper limit of normal.

Calpainopathy is a relatively common cause of LGMD. Norwood et al (2) recognized LGMD2A as the most common form of LGMD in the northern English population, with a prevalence of 0.60/100,000 (26.5% of the total LGMD group), similar to what was reported in an unselected LGMD population (39%) as well as in the Italian population (28.6%), with a carrier frequency in the north-eastern Italian population of ~1:160 (128,140). Founder effects are, in part, responsible for the higher prevalence observed in Turkey, Basque Country, and Russia, as well as in La Reunion, where the prevalence of calpainopathy is estimated to be 48/1,000,000.

Diagnosis of LGMD2A can be challenging. Immunoblot is currently the preferred laboratory test to assist the diagnosis (Figure 125-5). Protein analysis on muscle biopsy could be difficult to interpret, as the results of muscle immunoblotting are often complex and several calpain 3 bands could be detected, all susceptible to degradation, as the protein may have poor stability in experimental conditions. Immunohistochemistry with exon 1 monoclonal antibody can be useful for distinguishing the majority of genuine calpain 3 defects from secondary protein reduction (146). It has been suggested that, in cases with normal immunoblotting (Figure 125-5), further investigation of the autoproteolytic function of calpain 3 may offer an alternative route to diagnosis (147,148). In calpainopathy, examination of dystrophin, the sarcoglycans, and all other muscle proteins appear normal. It has to be noted, however, that secondary reduction in calpain 3 levels has been described in patients with a primary dysferlinopathy, reflecting an interaction between these proteins (149). The possibility of other, as yet unrecognized, secondary causes of reduction of the protein is another reason to confirm the diagnosis by mutation analysis.

The demonstration of mutations in the *CAPN3* gene is the gold standard to confirm calpainopathy, though this may be guided by linkage to chromosome 15 in families where the structure is suitable. Mutations in *CAPN3* may be missense or nonsense substitutions, small deletions or small insertions, spread widely over the gene (although missense mutations are relatively infrequent in the first protein domain and some exons remain free of mutations). A few recurrent mutations have been reported, with a mutation in exon 22 (c.2362\_2363delAGins TCATCT) accounting for over 30% of chromosomes analyzed by Saenz et al (144). One mutation does appear to be conserved with a founder haplotype in families from such diverse geographical origins as America, Brazil, and Reunion. Common mutations in some populations are due to founder effect. Unfortunately, around 23% of cases with LGMD2A only have one mutation found by commonly used mutation technologies. Sequencing of *CAPN3* transcripts present in muscle or peripheral blood

could be applied as a new approach for LGMD2A diagnosis, although lack of exon 15 in isoforms expressed in blood and presence of mRNA degradation would suggest the combined use of mRNA and DNA analyzes (150,151). Detection of the causative mutation is also necessary for carrier detection and prenatal diagnosis when required (144,148).

Genotype–phenotype correlations are difficult except in patients who are homozygous for a *CAPN3* mutation; as a general rule, patients with homozygous null mutations tend to have the most severe clinical course, in particular with regard to age at loss of ambulation. Although there are occasional reports of elevated CK in carriers especially, it has been suggested, in carriers of a particularly deleterious mutation, the general applicability of this has yet to be determined.

Calpain 3 is the muscle-specific member of a family of calcium-dependent proteases. It has four protein domains similar to those found in ubiquitous calpains, as well as three unique regions (NS, IS1, and IS2) possibly conferring its muscle specificity. It is still unclear how a *CAPN3* mutation causes muscular dystrophy, but various insights are emerging. Indeed, *CAPN3* mutations frequently lead to protein loss from skeletal muscle, and loss of proteolytic function is a common consequence of *CAPN3* mutations (147,148). Calpain 3 interacts with titin through one of the IS2 muscle-specific sequences, which also contains a nucleus translocation signal-like sequence (152). Calpain 3 is located in both the cytosol and the nucleus, suggesting that it may have a role in regulating levels of muscle-specific transcription factors and muscle cell differentiation. An apparent increase in apoptosis has been described in calpain 3-deficient muscle. A defect in sarcomere remodeling with loss of ubiquitination has also been described (152). Calpain 3 coexists in the dysferlin protein complex with AHNK, a protein involved in subsarcolemmal cytoarchitecture and membrane repair. AHNK is cleaved by calpain 3 and lost in cells expressing active calpain 3. Conversely, AHNK accumulates in muscles from patients with LGMD2A. The AHNK fragments cleaved by calpain 3 lose their affinity for dysferlin suggesting an interconnection between LGMD2A and LGMD2B (153).

#### 125.5.2.2 LGMD2B or Dysferlin Myopathies.

Dysferlinopathies are a heterogeneous group of recessive muscular dystrophies, ranging from a predominantly proximal disease (LGMD2B), a more posterior and distal phenotype predominantly affecting the gastrocnemius, the Miyoshi myopathy (MM), to rarer phenotypes such as a distal myopathy, affecting the anterior tibial muscles (154), or isolated hyperCKaemia. LGMD2B and MM are the most common presentations, observed in about half of patients with dysferlin (*DYSF*) mutations only, but unusual phenotypes are indeed common (155). No significant differences are observed in progression rate, functional prognosis, MRI pattern of muscle involvement, or *DYSF* mutations between patients with MM

and LGMD2B, favoring the merging of these diseases into a unique clinical continuum called dysferlin myopathy (156). Corroborating this conclusion is the observation of families with affected members presenting with different phenotypes.

Patients affected by dysferlin myopathies are often very active and sporty before the onset of symptoms. About 25% of patients have first symptoms before the age of 13 years with a window from 17–25 years (156), although rare congenital (157) as well as late onset in elderly has also been described (158). Independent of the initial mode of presentation, gastrocnemius appears to be the most severely affected muscle leading to an inability to stand on tiptoes, and lower limbs are affected more severely than upper limbs (159) (Figure 125-11). In contrast to LGMD2A, scapular involvement is minor and is not present at the onset. Conversely, a distinct “bulge” of the deltoid muscle is a striking feature of the disease. Calf hypertrophy as a transient feature early in the course of the disease has been reported in a minority of patients, and temporary painful swelling of the calf is another unusual presentation. Calf wasting is also commonly seen, while early contractures are rare. Progression is generally slow, and there is not a consistent relationship between mode of presentation and subsequent progression. Cardiac and respiratory functions are usually preserved. CK is usually massively increased up to 100 times the upper limit of normal.

Prevalence of dysferlinopathy varies among populations. The disease appears to be more prevalent in southern than northern Europe and Japan (160–163). In Italy, frequency of LGMD2B is indeed high (18.7%) being second only to LGMD2A (128). Conversely, in northern England dysferlinopathy is less common at 5.9% with a prevalence of 0.13/100,000 (2).

Muscle biopsies show generally nonspecific dystrophic changes, although inflammatory features are also often prominent, leading to polymyositis having been a frequently considered differential diagnosis. Demonstration of loss of dysferlin labeling in muscle biopsies is an extremely useful guide to which patients are to be analyzed for mutations (Figure 125-5). Dystrophin and sarcoglycan analysis in these patients is normal. In approximately half of the dysferlinopathy patients so far studied, calpain 3 levels on immunoblotting are reduced, and caveolin 3 immunolabeling may also be altered (164). Dysferlin can also be studied in monocytes (165).

The LGMD2B locus was first identified in families with a predominantly proximal muscular dystrophy with onset in the late teens (166,167). The gene for MM was shown to localize to the same genetic interval on chromosome 2 as LGMD2B, and subsequent analysis has confirmed the two disorders to be allelic. Not all cases of MM are associated with *DYSF* mutations, with a second locus tentatively assigned to chromosome 10.

Diagnosis of dysferlinopathy is based on detection of *DYSF* gene mutations. Linkage to chromosome 2p13 in

large families may be indicative of the diagnosis. The *DYSF* gene has 55 exons and three alternative exons (1, 5a and 40a), and encodes a 230-kDa ferlin-1 like protein. *DYSF* has a large mutational spectrum, but unfortunately, the detection rate is incomplete. Mutations in dysferlin are spread widely over the coding sequence of the gene, but alternative exons 1, exon 5a, and exon 40a show no disease-causing mutations (168). A particularly prevalent *DYSF* mutation is present in approximately 10% of the Libyan Jewish population. Founder mutations have also been recognized in Spain and Italy, in part responsible for the higher prevalence in these populations (160,162). The possibility of internally deleted functional dysferlin protein has been suggested by the description of mildly affected patients missing one or more *DYSF* exons (169,170). Thus, exon skipping might also be applicable for dysferlinopathy. It has been indeed shown that *DYSF* exon skipping could be as straightforward as DMD exon skipping, as AONs to induce efficient skipping of four *DYSF* exons were readily identified (171).

Carriers of a single *DYSF* gene mutation can rarely be symptomatic (172). No genotype–phenotype correlations are recognized. These findings, together with the wide clinical heterogeneity and the intrafamilial variability, suggest that additional factors, either genetic or nongenetic, may contribute to the pattern of the muscle involvement observed.

Dysferlin is a member of a novel mammalian gene family with homology to a nematode protein (FER-1) involved in spermatogenesis. Another FER-1-like gene (otoferlin) is involved in autosomal recessive deafness, whereas the third human member of this novel gene family, myoferlin or FER-1L3, which is highly homologous to dysferlin, is not yet associated with any human disease but may be upregulated in some forms of muscular dystrophy. The proteins in this group share the structural features of multiple C2 domains, with a C-terminus transmembrane domain. Dysferlin localizes predominantly to the muscle fiber membrane and shows weak interactions with caveolin 3, the annexins and calpain 3 (149,173–175). It is expressed from very early in human development and also in the placenta. Dysferlin is the first example of a protein containing multiple C2 domains, being involved in a muscular dystrophy phenotype, and defines a novel mechanism for the production of a muscular dystrophy via the disruption of the mechanisms for muscle membrane repair (176–180). Dysferlin also plays an important role for muscle membrane maintenance and integrity, and recent data support the role of dysferlin in vesicle trafficking, phagocytosis, focal adhesion, and myogenic differentiation (181). In view of the muscle inflammation often observed in LGMD2B patients, it has been hypothesized that a dysfunction of monocytes and macrophages might contribute to disease pathogenesis and progression. Indeed, it has been observed that dysferlin deficiency enhances monocyte

phagocytosis, suggesting that the myofiber damage might stimulate an inflammatory cascade that can exacerbate the underlying dystrophic process (182). In addition, dysferlin also plays a role in muscle regeneration and maintenance, as well as neutrophil response. In addition to the muscle membrane repair model, dysferlin appears also to be involved in the release of chemotactic agents. In fact, in dysferlinopathy-reduced neutrophil recruitment results in incomplete cycles of regeneration, which together with the membrane repair deficit ultimately triggers dystrophic pathology (183). A predominantly cytoplasmic localization of dysferlin can be observed in regenerating myofibers in dysferlinopathy patients, but the subcellular compartment responsible for this labeling pattern is not yet known. Dysferlin associates with the developing T-tubule system *in vitro* and *in vivo*, and dysferlin-deficient muscle revealed primary T-tubule anomalies, indicating a role of dysferlin in T-tubule formation (184).

**125.5.2.3 LGMD2C-D-E-F or Sarcoglycanopathies.** LGMD2C–F are caused by mutations in one of the genes, encoding for protein of the sarcoglycan complex. The sarcoglycans are transmembrane proteins within the dystrophin-glycoprotein complex at the muscle cell membrane whose functions may include its stabilization, which may play a role in cell signaling. Primary genetic defects in one of four ( $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\delta$ ) sarcoglycans are now established as the cause for four subtypes of AR-LGMD (185,186). A fifth sarcoglycan ( $\epsilon$ -sarcoglycan), homologous to  $\alpha$ -sarcoglycan, appears to be maternally imprinted and is mutated in myoclonus-dystonia syndrome (187,188).  $\zeta$ -Sarcoglycan is not associated with any disease phenotype (189). Because loss or deficiency of any of at least four sarcoglycans causes muscular dystrophy, these proteins must play a critical role in the maintenance of membrane integrity through the maintenance of the link from the extracellular matrix to the proteins of the cytoskeleton and contractile apparatus. In  $\beta$ - and  $\delta$ -sarcoglycanopathies, there are also some indications that smooth vascular muscle disease may add to the dystrophic process, although this mechanism has not yet been fully established.

The clinical spectrum of sarcoglycanopathies overlaps with dystrophinopathies, with the distinction that learning difficulty is not seen in sarcoglycanopathies, and scapular winging is more frequent (Figure 125-11). Presentation may range from early childhood to late adulthood, and progression may be rapid or much more benign. Early presentation usually indicates more rapidly progressive disease, and childhood presentation predominates, being  $\alpha$ -sarcoglycan deficiency responsible for 22% of patients with a progressive muscular dystrophy beginning in childhood. Cases of LGMD2D ( $\alpha$ -sarcoglycan) with a late onset show indeed a milder course with respiratory insufficiency while patients are still ambulant (190). Up to 6% of adult-onset cases are  $\alpha$ -sarcoglycan deficient. Muscle hypertrophy is common,

and at presentation, patients show relatively great involvement of the scapular muscles and hamstrings. Cardiac and respiratory involvement is also reported alongside the progression of muscle weakness, similar to what seen in DMD. CK values are increased up to 10 times the upper limit of normal.

Prevalence of sarcoglycanopathy is variable. The combined frequency of sarcoglycanopathy in the northern England population is 11.7% with a prevalence of 0.27/100,000 (2), while frequencies in Italy were as follows: LGMD2C ( $\gamma$ -sarcoglycan) 4.5%; LGMD2D 8.4%; LGMD2E ( $\beta$ -sarcoglycan) 4.5%; LGMD2F ( $\delta$ -sarcoglycan) 0.7% (128). Prevalence of LGMD2D in Finland is higher (1:250,000) with a carrier frequency around 1:150 (191).

Muscle immunoanalysis using specific antibodies to the various sarcoglycans is the primary diagnostic tool. Use of antibodies against all four sarcoglycans for immunoanalysis of skeletal muscle sections is recommended, as residual sarcoglycan expression is highly variable and does not enable an accurate prediction of the genotype (192). Multiplex Western blotting may also be very helpful in trying to resolve the primary abnormality (Figure 125-5). A concomitant reduction of dystrophin and  $\beta$ -dystroglycan is also frequently observed and illustrates the important differential diagnosis of DMD and BMD for sarcoglycanopathies (193). The most worrying diagnostic confusion may be with isolated women with muscular dystrophy who, if a full range of antibodies is not used, may be misdiagnosed as manifesting carriers of DMD, with potentially disastrous results for genetic counseling (193). In addition, the issue of misdiagnosis in men (between BMD and sarcoglycanopathy) can also be important (Figure 125-10).

Mutation analysis is necessary in order to provide carrier testing or prenatal diagnosis. Mutations identified in the *SGCA* gene on chromosome 17q21, coding for the 50-kDa  $\alpha$ -sarcoglycan (previously called adhalin), cause the most commonly reported sarcoglycanopathy (LGMD2D). LGMD2E, LGMD2C, and LGMD2F are caused by mutations in the *SGCB*, *SGCG*, and *SGCD* genes on chromosomes 4q12, 13q12, and 5q33, respectively. A wide range of mutations has been described in the four sarcoglycan genes. Many mutations are missense, and most are found in the portion of the genes, encoding the large extracellular domains. A CpG site in exon 3 of the *SCGA* represent a mutation hot spot, being mutation R77C the most frequently reported. Various founder mutations are also described. Not all patients with absent or reduced sarcoglycan staining on a muscle biopsy can be shown to have a mutation in one of the sarcoglycan genes by standard techniques, in particular sequencing (193). Exclusion of large deletions may be useful in these cases. In particular, MLPA analysis is able to detect copy number changes in about 15% of tested cases, with *SGCG* gene accounting for 8% of cases, as

the size of the gene makes it vulnerable to large exonic deletions (193).

It has been suggested that missense mutations in these membrane proteins may lead to aberrant protein processing and degradation. From this model, missense mutations in a member of the complex might cause improper processing or assembly of the whole group, leading to rapid turnover of the mutated protein. In  $\beta$ - and  $\delta$ -sarcoglycanopathy, disruption of the smooth muscle sarcoglycan complex may contribute to the development of cardiomyopathy (185). Indeed, rare cases of hemizygous  $\delta$ -sarcoglycanopathy have also been reported with an isolated cardiomyopathy phenotype (194), and in particular, the S151A mutation has been reported to cause severe lethal form of dilated cardiomyopathy. The same mutation was also detected in a consanguineous family with LGMD also segregating a homozygous novel missense mutation in the same gene in exon 6 (A131P) (195). Compound heterozygous family members revealed no signs of cardiomyopathy, questioning thereby the role of the *SCGD* gene in general as a disease-causing gene for autosomal-dominant dilated cardiomyopathy.

Mendell et al. (196) have shown use of gene therapy as a potential treatment approach for LGMD2D. In fact, they attained long-lasting sustainable gene expression of  $\alpha$ -sarcoglycan in LGMD2D subjects mediated by adeno-associated virus gene transfer under control of a muscle-specific promoter.

**125.5.2.4 LGMD2I and 2K.** LGMD2I is one of the most frequent forms of LGMDs, and the protein involved is the fukutin-related protein (FKRP). Mutations in the *FKRP* gene cause a remarkable spectrum of disease severity, from a severe congenital muscular dystrophy to a mild form of LGMD (197,198). FKRP belongs to a growing family of proteins involved in producing muscular dystrophies that are involved in the O-glycosylation of  $\alpha$ -dystroglycan. Disruption of the link through the muscle fiber mutation through  $\alpha$ -dystroglycans is a novel and increasingly important mechanism for producing muscular dystrophy (199–201).

LGMD2I is the most common form of LGMD in northern Europe (138,139,202) with a common founder mutation (C826A) in this population, which is also present in the Hutterite population of Canada (203). Minimum prevalence in the Norwegian population is 1/54,000 with a carrier frequency of 1/116 (203). In northern England, LGMD2I represents 19.1% of the total LGMD group with a prevalence of 0.43/100,000 (2).

Presentation can be at any age, with a spectrum of disease severity similar to that seen in dystrophinopathy. The ability to identify LGMD2I has brought to light some misdiagnoses amongst the supposed DMD and BMD population, critical for genetic counseling, and highlighting the importance of full genetic diagnosis in all cases (138). Clinical clues for diagnosis are hypertrophy of the calf and sometimes other muscles (including the tongue),

as well as cardiomyopathy (reduced left ventricular ejection fraction) and diaphragm involvement that could cause particular problems with breathing when lying flat (Figure 125-10 and 125-11). Cardiac and respiratory involvement carries indeed important implications for medical surveillance and treatment, and patients often require respiratory support even when the patient is still ambulant (137,204). Oligosymptomatic patients and individuals with predominant cardiac involvement have also been described, with cardiomyopathy being the first sign of the disease (204). Gene mutation and the severity of the muscle disease are usually not predictive of cardiac involvement. Abnormal glycosylation of  $\alpha$ -dystroglycan in LGMD2I may interfere with brain development and cognitive performances, involving the frontal and posterior parietal regions, but does not result in specific brain MRI abnormalities (205).

LGMD2K also involves glycosylation defects and is caused by mutations in the *POMT1* gene. LGMD2K is allelic to a severe form of CMD (see “Congenital muscular dystrophies”). Patients appear to have mental retardation as well as muscular dystrophy. This disorder is common in Turkey (206).

Examination of the muscle biopsy in patients with LGMD2I and LGMD2K typically shows a secondary reduction in  $\alpha$ -dystroglycan (Figure 125-4), with a secondary reduction in laminin  $\alpha$ -2 on immunoblotting. The diagnosis of LGMD2I is through mutation analysis of the *FKRP* gene. The vast majority of LGMD2I cases (typically all cases in northern Europe) have at least one copy of the common C826A mutation, while *FKRP* mutations found in CMD are much more variable (for more details see “Congenital muscular dystrophies”). If the *FKRP* gene was normal in patients with LGMD and abnormal  $\alpha$ -dystroglycan, it would be appropriate to direct mutation detection to the other genes involved in glycosylation of  $\alpha$ -dystroglycan. It is likely that milder mutations in all of the genes also involved in CMD phenotypes will eventually be described in LGMD, as for LGMD2I and LGMD2K.

**125.5.2.5 LGMD2G.** LGMD2G is a rare form of LGMD representing about 3% of all LGMDs, and it has been so far observed mainly in patients from Brazil and Italy. The phenotype can be more variable than that initially suggested. Clinically, patients between ages 9 and 15 years present with difficulty climbing stairs and running, although foot drop is also an early feature. Proximal and distal lower limb weakness is present from the onset, whereas in the upper limbs, the proximal musculature is usually more severely affected. Confinement to a wheelchair usually occurs after the 4th decade. Females appear to be less severely affected than males. Cardiac involvement is frequent. CK levels are elevated to 3–30 times.

The locus for LGMD2G was identified in 17q11–12 through the study of large LGMD families in Brazil, and mutations in the telethonin gene, which encodes a sarcomeric protein, are now known to be responsible for

this form of LGMD (1). Examination of muscle biopsies shows a large number of rimmed vacuoles (a feature not commonly reported in AR-LGMD) and loss of telethonin labeling. Diagnosis needs to be confirmed by mutation analysis.

**125.5.2.6 LGMD2H.** This disorder was first described in 1976 in the Hutterite population in Manitoba, and it is caused by a founder homozygous mutation (D487N) in the E3 ubiquitin ligase *TRIM32* gene (207,208). One sib pair has been identified in a non-Hutterite family in Germany (the country of origin of the Hutterites). Affected individuals are described as presenting usually with proximal lower limb weakness with a variable age at onset (from early childhood to mid-20s). Facial weakness is observed as the disease progresses. Mild distal limb involvement is also seen, involving the brachioradialis and anterior peroneal muscles, but most patients remain ambulant late into adult life. CK values are typically elevated up to five times the normal values. Muscle biopsy analysis shows no pathognomonic changes, and diagnosis is based on identification of *TRIM32* gene mutations. Patients with sarcotubular myopathy, also of Hutterite origin, have now been identified to have *TRIM32* mutations, but this does appear to be a rare cause of muscle disease (209).

**125.5.2.7 LGMD2J.** LGMD2J is rare form of LGMD described only in Finland in very few cases, and it is caused by homozygous mutations in the titin *TTN* gene, representing the severe form of the milder tibial muscular dystrophy. LGMD2J is characterized by severe progressive proximal weakness, with onset ranging from the 1st to the 3rd decade. Weakness can also involve the distal compartments, and about half of the patients require the use of a wheelchair. Contractures and cardiac or respiratory involvement are not reported. CK values are massively raised. On immunohistochemistry, severe reduction or absence of calpain 3 is detected, as reflection of the interaction of titin with calpain 3. Diagnosis is based on *TTN* gene analysis, and almost all affected individuals have a homozygous 11-bp deletion/insertion in the last exon termed Finnish FINmaj, being very common in the Finnish. Recently, a novel mutation has been described in a French family (210).

**125.5.2.8 LGMD2L.** LGMD2L is caused by mutations in the *ANO5* gene, which encodes a putative calcium-activated chloride channel belonging to the Anoctamin family of proteins. Mutations in *ANO5* were first identified in families with LGMD2L and non-dysferlin MM (211). Screening of additional cohort of patients from England and Germany showed that LGMD2L is indeed is relatively common form of LGMD (212). In particular, a truncating mutation (c.191dupA) in exon 5 of *ANO5* has been identified in homozygous or combined heterozygous state in all patients from these cohorts, suggesting a founder effect for this mutation in the northern European population. Patients with LGMD2L show adult-onset (from early 20s to 50s) proximal lower limb weakness

with highly raised CK values (average 4500 IU/l). Distal presentation is much less common, but a milder degree of distal lower limb weakness is often observed. Muscle wasting mainly affects quadriceps, hamstrings, and the medial gastrocnemius (Figure 125-11). Knee hyperextension is a common and often causes progressive functional disability. Asymmetry of muscle weakness and atrophy is common (90% of patients) and represents, together with thigh muscle atrophy and later age at onset, a useful predictor to differentiate LGMD2L from LGMD2B. The weakness is generally slowly progressive, with most patients remaining ambulant for several decades. In later stages of the disease, mild weakness and wasting of the upper limbs, in particular of biceps brachii and brachioradialis, are also observed. Cardiac and respiratory function is normal. Intrafamilial variability in mode of presentation and disease progression is also observed, and CK measurement and molecular testing could be used to identify asymptomatic or mildly affected family members. Females represented a minority of cases of the mutation positive patients and appear to be less severely affected, suggesting a strong bias toward affected males in the LGMD2L population.

A predominantly distal phenotype is more often observed in association with other *ANO5* mutations, and one in particular appears common in the Finnish population. The phenotype observed in the Finnish patients is characterized by onset in the third decade, with first symptoms being burning sensation on the calves and, later on, calf tightness during running. Muscle weakness and wasting were asymmetric and early involving the calf muscles, later spreading to the thigh muscles. Involvement of biceps brachii was a later manifestation (213).

Although the same *ANO5* mutation can also lead to a variable clinical presentation at onset (LGMD or distal myopathy), with disease progression, the phenotypes largely overlap and merge into a more homogenous clinic entity.

The minimum prevalence of LGMD2L in the North of England is 0.27/100,000, being the 3rd most common form of LGMD. The apparent frequency of this condition in this group compared with some of the other forms of LGMD confirm the need to incorporate *ANO5* mutation screening (at least for the common mutation) at an early stage in the diagnostic algorithm for patients presenting with an LGMD phenotype.

*ANO5* encodes a member of the anoctamin family of proteins, which contain eight transmembrane domains. Dominant mutations in the *ANO5* gene are associated with the skeletal disorder called gnathodiaphyseal dysplasia (214). The role of *ANO5* is still unknown, but the homologous proteins *ANO1* and *ANO2* are known to be calcium-activated chloride channels (215–219). However, it has been suggested that *ANO5* may be important in the development and maintenance of skeletal muscle and the clinical overlap between LGMD2L and

LGMD2B further suggests that mutations in *ANO5* may be involved in membrane repair.

**125.5.2.9 Other Causes of Autosomal Recessive Limb-Girdle Muscular Dystrophy.** The list of AR-LGMD genes does not yet appear to be completely exhaustive, and other rare forms of LGMDs, allelic to CMD, are caused by mutations in the *FKTN* (LGMD2M), *POMT2* (LGMD2N), and *POMGNT1* gene (LGMD2O) (1). An additional form of AR-LGMD associated with cognitive impairment has been now linked to a mutation in the *DAG1* gene encoding dystroglycan (220). Moreover, mutations in the *PLEC1* gene, also responsible for epidermolysis bullosa simplex with muscular dystrophy, have been identified in a consanguineous Turkish family (221). This new form of LGMD has now been coded LGMD2Q (<http://omim.org/entry/613723>). In populations with a high rate of consanguinity, the possibility of further loci is suggested by the existence of families that are still unlinked to any of the known genes. Use of the full battery of investigative tools in all patients with a suggestive phenotype will no doubt reveal other presumably secondary protein deficiencies. The key role of the muscle biopsy in elucidating both primary and secondary effects in LGMD is very clear, and in all patients with suspected LGMD, this investigation should be recommended, with frozen tissue kept available for further analyzes as these become available.

## 125.6 MYOFIBRILLAR MYOPATHIES AND OTHER DISTAL PHENOTYPES

### 125.6.1 Myofibrillar Myopathies

**125.6.1.1 Clinical Features.** Myofibrillar myopathies (MFMs) represent a clinically and genetically heterogeneous group of conditions characterized by a similar distinctive myopathological phenotype of myofibrillar dissolution and myofibrillar degradation products, giving the name to these conditions. So far, mutations in eight different genes (*DES*, *MYOT*, *CRYAB*, *FLNC*, *ZASP*, *BAG3*, and *FHL1*) have been described in MFM or MFM-like conditions (118). FHL1-related myopathy is covered separately in view of its contractural phenotype. Inheritance of MFMs is autosomal dominant, although rare exceptions with autosomal recessive inheritance have been described (222). A significant number of patients with MFM are sporadic, and incomplete penetrance has also been observed.

The clinical phenotype of MFM is extremely variable and, in part, depends on the different molecular etiology, and several genotype–phenotype correlations have been drawn (118). In general, MFMs are characterized by progressive adult-onset muscle weakness involving more the distal than the proximal compartments. Onset can vary according to the underlying molecular defect. Classically, *DES* and *CRYAB* gene mutations associate with

an onset in early or mid adulthood, while *MYOT*, *ZASP* and *FLNC* gene mutations tend to manifest later in life, usually after the fourth or fifth decades. Congenital or childhood onset has been described in association with recessive *DES* and *CRYAB* gene mutations, as well as in families with *BAG3* gene mutations (222–225). Patterns of muscle weakness are variable. Distal onset in the lower limbs is the most common, followed by a more LGMD (with *MYOT* gene mutations), scapuloperoneal (with *DES* gene mutations), or a more general distribution of weakness. The weakness is progressive and later may involve facial, truncal and neck muscles and can also cause swallowing difficulties and dysarthria, in particular with *DES*, *CRYAB*, and *MYOT* gene mutations. Cardiac and respiratory involvement is common, as well as involvement of other organs and apparatus, such as skin, joints, and nervous system. Cardiac disease, mainly arrhythmias (AV nodal conduction blocks, supraventricular and ventricular ectopic beats, tachycardia) and/or cardiomyopathy (dilated, hypertrophic, or restrictive), is observed in up to 30% of individuals, most commonly in association with *DES*, *ZASP*, and *BAG3* gene mutations. *DES* and *BAG3* gene mutations have also been reported in patients affected by isolated cardiomyopathy (226,227). Treatments include pacemaker and implantable cardioverter defibrillator as well cardiac transplantation in case of life-threatening cardiomyopathy (223). Respiratory insufficiency, caused by weakness of respiratory muscles, is common in particular in patients with *FLNC* and *BAG3* gene mutations. Joint contractures and/or rigid spine are observed in patients with *BAG3*, *MYOT*, as well as in rare patients with *DES* or *CRYAB* gene mutations with congenital or early-childhood onset. Neuropathy has been reported in patients with *BAG3*, *ZASP*, or *FLNC* mutations. Cataract has been observed in three families with *CRYAB* gene mutations. CK levels are usually normal or moderately elevated, but marked increases were also observed in association with *BAG3* and *MYOT* gene mutations. EMG is usually myopathic although rare cases of mixed myopathic and neuropathic findings have also been observed.

Mutations in two further genes (*TTN* and *DNAJB6*) have recently been identified in families segregating an autosomal dominant myopathy and showing histopathological changes such as eosinophilic inclusions, rimmed vacuoles, and Z-disc abnormalities, suggestive of MFM (132,133,228,229). A single heterozygous mutation in the A-band of Titin was detected in a few dominant families. The phenotype is mainly characterized by predominant distal, proximal, and respiratory weaknesses, with variable age at onset, CK being normal or increased up to 4–5 times the normal values (228,229). As previously mentioned, the phenotype associated with *DNAJB6* mutations is also characterized by distal and proximal weakness, but no major respiratory or cardiac involvement was found in the few families described so far (132,133).

Diagnosis of MFM is greatly based on observation of myopathological findings. In addition to myopathic changes, usual findings are subsarcolemmal and/or sarcoplasmic protein aggregates, cytoplasmic bodies, rimmed and nonrimmed vacuoles, and core-like lesions (230,231). Specific findings can give an indication of the underlying molecular defect. Not all MFM biopsies show the above-mentioned findings, and unspecific and normal muscle biopsy analyses have also been observed in genetically confirmed MFM patients. Immunostaining using antibodies for desmin, myotilin and  $\alpha$ B-crystallin shows pathological protein aggregation and it is commonly used in diagnostic laboratories (Figure 125-4). Western blot analysis is usually nondiagnostic, except for rare cases of truncating, X-linked or recessive mutations. EM analysis shows pathological protein aggregation and myofibrillar degeneration.

**125.6.1.2 Genetics and Pathogenesis.** The genetic bases of MFM are only partially known. Mutations in the known genes are responsible for about 50% of MFM cases and being *MYOT* and *ZASP* gene mutations the most common (13 and 14%, respectively) followed by *DES* (8%) and then by *CRYAB*, *FLNC* and *BAG3* genes mutations, each responsible for 4% of cases (232). Prevalence of *TTN* and *DNAJB6* mutations in MFM patients is not known, to date.

Most of MFM patients are sporadic or with a dominant family history. Germ line mosaicism has been described in families with multiple affected siblings, harboring heterozygous *BAG3* gene mutations (226). Recessive mutations in the *DES* and *CRYAB* genes have been reported in a few families with atypical or more severe presentations (222,233), with heterozygous parents showing no clinical symptoms. Prenatal and preimplantation genetic testing could be offered in families with known mutations.

Molecular pathogenesis may vary according to the underlying genetic defect. In general, disease proteins are involved in maintaining the structural integrity of the Z-disk. Desmin is a type III intermediate filament protein present in striated and smooth muscle cells. Desmin has a tripartite structure with a central  $\alpha$ -helical coiled-coil rod domain, flanked by non- $\alpha$ -helical head and tail domains. The rod domain plays a key role in the assembly of desmin filaments and formation of extrasarcomeric cytoskeleton, forming a three-dimensional scaffolding structure of the Z-disks, interlinking myofibrils and connecting them to the nuclei, mitochondria, and sarcolemma. For its proper function, desmin interacts with other binding proteins such as plectin and  $\alpha$ B-crystallin. Myotilin, Filamin C and *ZASP* are key Z-disk proteins interacting with each other or with other Z-disk or sarcolemmal proteins. *BAG3* is a cochaperone for the Z-disk with antiapoptotic properties. *DNAJB6* interacts with this, and other proteins involved in chaperone-assisted selective autophagy and current data suggest that *BAG3* might indeed have a role in mediating the pathogenic effect of *DNAJB6*

mutations (133). Defects in MFM proteins therefore cause disintegration of the Z-disk, leading to myofibril degeneration. Metabolic abnormalities have also been reported, in particular based on the mitochondrial pathology, protein quality control mechanisms related to the ubiquitin–proteasome system, and the autophagolysosomal pathway.

## 125.6.2 Inclusion Body Myopathy Associated with Paget Disease of the Bone and Frontotemporal Dementia

**125.6.2.1 Clinical Features.** Inclusion body myopathy associated with Paget disease of the bone (PDB) and frontotemporal dementia (FTD) is a rare adult onset condition, characterized by proximal and distal muscle weakness, early onset PDB and premature frontotemporal dementia (IBMPFD) (234). Prevalence of IBMPFD is unknown, but it is probably an under-diagnosed condition. The myopathy is usually characterized by adult onset (20–40s) progressive weakness usually with proximal LGMD distribution. However, a distal onset involving hands and feet has also been described. Muscle weakness progresses to limb and respiratory muscles, and in later stages, the disease can lead to loss of ambulation. Cardiac failure due to cardiomyopathy is observed in later stages of the disease and together with respiratory failure is the prevalent cause of death, usually occurring in the sixth or seventh decade. About half of the affected individuals also show PDB, characterized by focal areas of increased bone turnover, leading to bone pain, localized painful bone enlargement and deformities of long bones, rare fractures, and deafness. PDB is often asymptomatic and is usually diagnosed based on increased alkaline phosphate concentration, with a mean age at diagnosis of 42 years. FTD is characterized by degeneration of the frontal and anterior lobes controlling reasoning, personality, movement, speech, social graces, and language, being memory unaffected. FTD affects about 1/3 of patients with IBMPFD with a mean age at onset of 55 years. A single family with prominent sphincter disturbance involving bladder, bowel, and erectile function in all affected individuals has also been reported (235), possibly caused by spinal cord and nerve pathology and consistent with pathological findings of spinal cord inclusion bodies (236).

Clinical diagnosis of IBMPFD is based on the combination of the major manifestation of the disease: myopathy, PDB, and FTD. However, only a minority of all affected individuals (12%) shows all the three major manifestations of the disease, while about 50% shows two, and about 30% of patients only show myopathy. CK values are normal or mildly elevated. EMG is myopathic. Muscle analysis shows degenerating fibers, rimmed vacuoles, and sarcoplasmic inclusions, containing ubiquitin and TAR DNA-binding protein 43.

**125.6.2.2 Genetics and Pathogenesis.** IBMPFTD is caused by heterozygous mutations in the VCP gene, encoding valosin-containing protein (VCP) (237). The VCP gene, localized on chromosome 9p, has 17 exons, and mutations (all missense) have been described mainly in the N-terminal CDC48 domain involved in ubiquitin binding. The majority of mutations are located in exon 5, in particular involving residue Arg155. Some genotype–phenotype correlations have been described (234,238). In particular, the Arg155Cys mutation has been associated with an earlier onset of IBM, while patients with the Arg155His mutation show a later onset of PDB (238). A more severe phenotype was observed in association with the Ala232Glu mutation in exon 6, involving a residue localized in the main catalytic D1 ATPase domain. Genetic heterogeneity has been shown, and several families with a clinical diagnosis of IBMPFTD (234) or overlapping phenotypes do not show linkage to 9p nor mutations in the VCP gene (239).

VCP is a 97-kD protein, and it is a member of the type II AAA ATPases that associate with a variety of activities, characterized by the AAA domains. VCP catalyzes ATP hydrolysis to generate energy and perform mechanical work in cells. VCP is involved in several cell cycle protein pathways, including ubiquitin-dependent protein degradation, and quality control process that eliminates aberrant proteins in the secretory pathway (240). VCP has been shown to participate in aggregate-prone proteins degradation, principally mediated by autophagy (241). Indeed, VCP mutations lead to accumulation of autophagic structures in patients and transgenic animal tissue, likely due to a defect in VCP-mediated autophagosome maturation (242).

### 125.6.3 Distal Myopathies

Distal myopathies (DM) are a heterogeneous group of muscle disorders characterized by weakness and atrophy starting from hands and feet, later involving lower legs and forearms. Although traditionally defined as myopathies, in view of the progressive nature of these diseases as well as of the typical histological changes, DMs are indeed muscular dystrophies. Genetic splitting and lumping has been observed, with mutations in the same gene responsible for different clinical phenotypes (243,244).

**125.6.3.1 Welander Distal Myopathy.** Welander distal myopathy (WDM) is a late-onset disease (40–60s), characterized by weakness first involving the index finger extensor. Initial lower leg involvement is observed in 1/3 of the patients, while proximal muscles are usually spared. Later, the disease can also involve the other finger extensors and flexors as well as the thenar and hand muscles. Ankle reflexes are lost in later stages of the disease. Asymmetry is commonly observed. MRI of lower legs shows fatty degeneration of the posterior and anterior compartments. CK levels are normal or increased up to 2–3 times the normal values. Muscle biopsy

analysis can show rimmed vacuoles but no inflammatory changes (245).

The inheritance of the disease is dominant, and it has been mainly reported in the Swedish and Finnish populations. A locus has been found in 2p13 with a unique founder haplotype in Scandinavian patients that could help for genetic counseling of families (246). Although extensive sequencing has been performed, no gene defect has been found, so far.

**125.6.3.2 Tibial Muscular Dystrophy.** Tibial muscular dystrophy (TMD) is a condition with a relatively high prevalence in Finland where it represents the most common muscle disease (10/100,000). TMD is a slow progressive disease, with onset in the late 30s. The first symptom is often an asymmetric weakness in ankle dorsiflexion, later associated with atrophy of the muscles of the anterior lower leg compartment. Typical sparing of extensor digitorum brevis as well as of hand muscles is a useful diagnostic handle. Late-onset proximal lower-limb weakness is observed, but loss of ambulation is a rare finding. MRI studies can show fatty degeneration of anterior tibial muscles, later also involving soleus and medial gastrocnemius. CK values are normal or mildly elevated. Muscle biopsy shows many rimmed vacuoles (243).

TMD is caused by heterozygous mutations in the titin (*TTN*) gene. Mutations typically involve the C-domain located in the M-line of the sarcomere. Finnish patients carry a common deletion–insertion in-frame mutation called FINmaj, while different point mutations were found in other populations. The mutated proteins are incorporated in the sarcomere, but they are likely lacking the whole C-terminus, as C-terminal antibodies do not recognize their epitopes. Dominant mutations therefore have a likely gain of function effect, different from what observed in the rare cases of homozygous *TTN* gene mutations observed in LGMD2J patients.

**125.6.3.3 Laing Distal Myopathy.** Laing distal myopathy (LDM) is a rare condition mainly characterized by mild foot drop and hanging of the big toe. The condition is clinically variable and onset may range from birth to the sixth decade (247). In addition to great toe/ankle dorsiflexors, weakness often interests the neck flexors, the finger extensors, as well as the facial muscles. Proximal and axial muscles are also affected clinically or by muscle imaging, with some patients showing scapuloperoneal or limb-girdle phenotypes from onset. Dilated cardiomyopathy, skeletal deformities, and myalgias have also been observed. The condition could be extremely mild with asymptomatic individuals or, more severe, with patients showing bone deformities, ankle contractures, and abnormal head posture, as well as loss of ambulation. CK is usually normal or moderately elevated (twice the normal limits). Most common pathological findings are predominance of atrophy/hypotrophy of type I fibers, core/minicore lesions, as well as mitochondrial abnormalities. MRI studies typically show involvement of the anterior compartment of the lower legs. EMG showed

frequent neurogenic features, in keeping with denervation–reinnervation activity, reflecting an abnormal motor unit remodeling process, and that could indeed lead to misdiagnosis (247).

Inheritance is autosomal dominant, and the condition is caused by mutations in the *MHY7* gene. The *MYH7* gene encodes for MyHC I or slow/ $\beta$ -cardiac myosin, and it is expressed in slow, type 1 muscle fibers as well as in the ventricles of the heart. To date, nine different mutations in the rod domain (between exon 32 and 37) have been described (244,247,248). Major clinical variability is observed in patients from the same family or with the same mutation.

**125.6.3.4 Distal Myopathy with Rimmed Vacuoles.** Distal myopathy with rimmed vacuoles (DMRV) or inclusion body myopathy type 2 (IBM2) is a rare condition characterized by distal lower limb weakness, with onset in late teens to early adulthood. Patients show gait disturbance with foot drop due to anterior tibialis muscle weakness. The weakness later involves proximal lower limb muscles and hands, but typically, but not constantly, spares quadriceps muscles. Shoulder muscles could be mildly affected, but triceps are spared. Neck flexors are affected. Rare patients with complete heart block have been reported. The condition is progressive, and after about 20 years of disease progression, patients usually become wheelchair bound. CK values are elevated up to 2–3 times the normal values. Muscle biopsy analysis shows rimmed vacuoles, with basophilic granular material on hematoxylin and eosin stain and purple-red with modified Gomori. It has been suggested that these represent autophagic vacuoles.

The condition has been described worldwide, but of the greatest majority of >200 patients so far described are from Iranian Jewish descendant or from Japan. Prevalence rate of the disease in Iranian Jews is estimated to be 1/500–1000. Inheritance is autosomal recessive and mutations of *GNE*, encoding for UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosaminase kinase, are the only known to be responsible for DMRV (249). In the middle-eastern Jewish population, 100% of patients carry a common missense change (M712T). Different mutations, including a large deletion, have been reported in different populations. No genotype–phenotype correlations have been described so far. Rare cases of lack of penetrance have been reported (250,251).

**125.6.3.5 Distal Nebulin Myopathy.** Distal nebulin myopathy is a rare condition, caused by homozygous mutations in the nebulin (*NEB*) gene (252). Affected individuals show childhood or adult-onset foot drop. Muscle weakness predominantly affected ankle dorsiflexors, finger extensors, and neck flexors, clinically resembling LDM. On muscle biopsy analysis, nemaline bodies are absent on routine light microscopy while inconspicuous or absent on EM. Rimmed vacuoles are also absent. The two reported missense mutations are localized in the C domain of nebulin and have been observed in

combination with more disruptive mutations in patients with nemaline myopathy.

**125.6.3.6 Kelch-Like Homolog 9 Gene-Related Distal Myopathy.** Cirak et al. described 10 affected members from a German kindred with a new form of DM (253). Affected individuals showed weakness and atrophy of the anterior tibial muscles leading to difficulty walking on heels and high stepping gait, with onset in late-childhood teens. Reduced sensation with stocking distribution in lower limbs has been observed in most of the patients. The weakness later spread to the intrinsic hand muscles and sensory symptoms in the hands have also been reported. Ankle joint contractures were also observed, likely secondary to the foot drop. CK levels ranged between 200 and 1400 IU/L. There was no evidence of a neuropathy on nerve conduction. MRI of lower limbs showed symmetric fatty atrophy of muscles and muscle biopsy showed myopathic findings. Genome wide analysis revealed a locus at 9p21.2–p22.3 that led to the identification of a heterozygous mutation in the Kelch-like homolog 9 gene, encoding for bric-a-brac Kelch protein.

**125.6.3.7 Matrilin 3-Related Distal Myopathy.** Mutations in *MATR3* gene, encoding matrilin 3, cause a new form of adult-onset, progressive autosomal-dominant DM, with dysphagia and dysphonia, also called vocal cord and pharyngeal weakness with distal myopathy (VCPDM). This condition has been first described and then mapped to chromosome 5q31 in a North American pedigree, and then fine mapping and sequencing of the critical interval allowed identification of mutations in the *MATR3* gene in two families (254). Matrilin 3, expressed in skeletal muscle, is a component of the nuclear matrix, a proteinaceous network extending throughout the nucleus. Mutations in *MATR3* do not appear as a common cause of muscular dystrophies (255).

**125.6.3.8 Other Forms of Distal Myopathies.** Mutations in genes responsible for muscular dystrophies with different distributions and phenotypes have also been associated with a more distal phenotype and could therefore be classified as pure DMs. Among these, the best examples are the genes responsible for MFMs and in particular *ZASP*, *VCP*, and *MYOT* genes (256–258) as well the *DYSF* gene, also responsible for the more distal Miyoshi myopathy phenotype (156).

## 125.7 CONGENITAL MUSCULAR DYSTROPHIES

### 125.7.1 Introduction

The congenital muscular dystrophies (CMD) are a clinically and genetically heterogeneous group of disorders, presenting at birth or within the first few months of life, with hypotonia, muscle weakness, contractures, and motor developmental delay. They are classically

described as having autosomal recessive inheritance; however, it has recently emerged that one form can also result from *de novo* dominant mutations. In the last decade, several new genes and proteins responsible for individual forms of CMD have been identified and the classification has expanded considerably.

### 125.7.2 Background

In 1993, an International Consortium on CMD proposed a classification based on clinical and imaging findings, defining four distinct phenotypes: (1) “classic” CMD; (2) Fukuyama congenital muscular dystrophy (FCMD); (3) muscle–eye–brain disease (MEB); and (4) Walker–Warburg (WWS). In contrast to the other three forms of CMD, “classical” CMD had no clinical evidence of central nervous system (CNS) or eye involvement. Also in 1993, the locus for FCMD was mapped to chromosome 9. The other forms of CMD with mental retardation and CNS or ocular involvement did not map to the FCMD locus. In 1994, an exciting discovery helped explain some of the clinical findings. A proportion of children with CMD were found to show an absence or marked deficiency in an extracellular matrix protein, merosin. This divided “classic” CMD into two groups: merosin deficient and merosin positive. Although the clinical spectrum associated with merosin-deficient CMD was relatively homogeneous, the merosin-positive group included several distinctive phenotypes, such as the Ullrich phenotype with distal laxity or the form with rigid spine, which in the last few years have been shown to be distinct genetic entities.

Another significant advance has recently come from the discovery that a number of forms of CMD with differing clinical phenotypes have in common a profound depletion of  $\alpha$ -dystroglycan, which can be demonstrated by immunolabeling. These forms, collectively categorized as dystroglycanopathies, have mutations in genes encoding known or putative glycosyltransferase enzymes, which among their substrates most likely include  $\alpha$ -dystroglycan.

To date, the genes responsible for more than 26 of those forms have been identified (Table 125-1). These forms can be classified into five main groups according to clinical, pathological, and genetic data:

1. CMD due to mutations in genes encoding structural proteins of the basal membrane or extracellular matrix of the skeletal muscle fibers. These include forms due to mutations in the genes encoding collagen VI, laminin  $\alpha$ -2 (merosin), and integrin  $\alpha$ -7 and integrin  $\alpha$ -9.
2. CMD due to mutations in genes encoding putative or demonstrated glycosyltransferases, which affect the glycosylation of  $\alpha$ -dystroglycan. These include FCMD, MEB, and WWS, and other forms with normal brain MRI, with and without mental retardation.

3. CMD with rigidity of the spine, due to mutations in the *SEPN1* gene, which encodes selenoprotein 1, an endoplasmic reticulum protein of unknown function.
4. CMD due to abnormalities of nuclear envelope proteins (Lamin A/C and nesprin).
5. CMD with mitochondrial structural abnormalities (CMDmt).

This classification includes only forms of CMD in which the primary genetic defect has been identified, but there are several other forms with distinctive phenotypes in which the underlying defect has not yet been identified. In this chapter, we describe in detail the forms of CMD most frequently found in clinical practice, such as merosin-deficient CMD and Ullrich CMD, followed by dystroglycanopathies and CMD with rigidity of the spine (RSMD1).

### 125.7.3 Merosin-Deficient Congenital Muscular Dystrophy

**125.7.3.1 Pathogenesis.** Merosin (laminin  $\alpha$ -2) is a subunit of laminin, a heterotrimeric extracellular matrix protein that links with dystrophin on the inner side of the muscle membrane through a group of dystrophin-associated glycoproteins (sarcoglycans and dystroglycans) that straddle the muscle membrane. Deficiency of merosin in this form of CMD results in loss of the critical linkage between the extracellular matrix and the intracellular actin-associated cytoskeleton. Merosin is expressed in the Schwann cell basement membrane in peripheral nerve, where it promotes neurite outgrowth and Schwann cell differentiation, migration, and adhesion (259). It is also expressed in the basement membrane of cerebral capillaries, and in neuronal processes of limbic brain regions and the cerebellum. Deficiency of merosin in these locations underlies the CNS and peripheral nervous system manifestations of this form of CMD.

#### 125.7.3.2 Clinical Features.

**125.7.3.2.1 Muscle Involvement.** Hypotonia is the most common presenting feature at birth or in the first months of life, followed by contractures and congenital dislocation of the hip. Neonatal respiratory and feeding problems may also occur. Motor development is delayed, and these children rarely achieve independent walking. Maximal motor ability is generally sitting unsupported and standing with support or, less commonly, walking with support. These children show respiratory problems as a result of diaphragmatic involvement and tend to develop nocturnal hypoventilation, sometimes associated with only moderately abnormal values of daytime oxygen saturation and forced vital capacity. Feeding problems and failure to thrive are also frequent. In our detailed study on 14 children (age range 2–14 years) with merosin-deficient CMD, 12 of the

14 children were below the third centile for weight. On videofluoroscopy only, the youngest child (2 years old) had a normal result, and five children required a gastrostomy.

The phenotype of the merosin-deficient group has expanded further with the recognition of other forms with atypical phenotypes but still with documented mutations in the *LAMA2* gene, such as a form with late onset.

**125.7.3.2.2 Central Nervous System Involvement.** White matter changes are a consistent feature in patients with merosin-deficient CMD. The changes are diffuse, resembling a leukodystrophy, and affect both hemispheres (Figure 125-12) but spare the internal capsule, corpus callosum, basal ganglia, thalami, and cerebellum. This pattern becomes more evident after 6 months but can be visualized in the neonatal period using appropriate MR sequences (260). In a proportion of children with merosin-deficient CMD, the white matter changes can be associated with structural brain changes, such as cortical dysplasia or cerebellar hypoplasia. Children with isolated white matter changes usually have associated normal cognitive function, but they may have mild perceptuomotor difficulties, when compared with both normal controls and children with CMD and normal scans. In contrast, the patients with white matter changes and additional cerebellar hypoplasia often have lower scores on the performance scales on cognitive tests. Epilepsy is common and may occur in about 20% of the cases. Visual function is normal, but visual evoked responses are generally abnormal.

**125.7.3.2.3 Peripheral Nervous System Involvement.** Merosin is expressed in the basement membrane of Schwann cells, and a demyelinating neuropathy is a feature of merosin-negative CMD, which can be

demonstrated by reduced peripheral motor nerve conduction velocity (261).

**125.7.3.3 Muscle Pathology.** The muscle biopsy shows a wide variation in fiber size and an increase in endomysial connective tissue and adipose tissue. Immunofluorescence techniques can readily demonstrate the reduction or absence of laminin  $\alpha$ -2. In some cases, the merosin is totally absent; in others, traces are present, but it is still markedly reduced compared with normal controls. The reduction of the merosin chain can sometimes be demonstrated only by the combined use of antibodies to both the globular 80-kDa components, which contain the C-terminal end, and to the 300-kDa N-terminal end. Laminin  $\alpha$ -2 can be also demonstrated in the skin, and a skin biopsy can provide useful information when muscle is not available.

**125.7.3.4 Molecular Genetics.** Merosin-deficient CMD is autosomal recessively inherited. The 64-exon *LAMA2* gene is located on chromosome 6q22–23. Most mutations causing complete merosin deficiency are non-sense or frame-shifting mutations. These are predicted to encode truncated proteins lacking the C-terminal G domain that is involved in  $\alpha$ -dystroglycan and integrin binding, sometimes together with the preceding coiled-coil forming domains that are required for assembly of the laminin heterotrimer (262,263). Mutations are scattered throughout the length of the gene, and the only common mutation is a 2-bp deletion, 2098delAG (703X), which has been reported in several families of different nationalities (264). Recently, two siblings with strikingly different clinical phenotypes were described who were both homozygous for the same out-of-frame deletion in *LAMA2*. Both had complete merosin deficiency in muscle, but one had a classical merosin-deficient CMD phenotype, whereas the other had milder muscle weakness and was still ambulant aged 13 years (265). Modifying

**FIGURE 125-12** Merosin-deficient boy 7 years of age. T2-weighted SE 2500/80 sequences. A, Low ventricular level showing abnormal, increased signal intensity in a periventricular distribution. Note that the white matter of the basal ganglia is spared. B, Centrum semiovale, showing extensive white matter lesions. (From Philpot, J.; Topaloglu, H.; Pennock, J.; Dubowitz, V. *Familial Concordance of Brain Magnetic Resonance Imaging Changes in Congenital Muscular Dystrophy*. *Neuromuscul. Disord.* 1995, 5, 227–231).

genes might have affected the clinical phenotype in this family.

Patients with partial merosin deficiency have a variety of mutations including missense and non-sense mutations, splice-site mutations (resulting in exon skipping or altered splicing efficiency), or small, in-frame deletions (262,266,267). These are mostly predicted to result in expression of a partially functional protein or low levels of a normal protein, in contrast to the situation in complete merosin deficiency, in which mutations result in a truncated, nonfunctional protein.

A recent paper examining the relationship between degree of merosin expression, genotype, and clinical features in 51 patients with MDC1A has reported that *LAMA2* mutations were distributed throughout the gene in patients with absent merosin and more severe phenotype, with minor clusters in exon 27, 14, 25, and 26 (55% of mutations). Patients with residual merosin and milder phenotype often carried at least one splice-site mutation and less frequently frameshift mutations (268).

**125.7.3.5 Genetic Counseling.** A diagnosis of merosin-deficient CMD can be confirmed by *LAMA2* mutation analysis or by linkage analysis in suitable families, and these families can be offered antenatal diagnosis. Merosin is expressed in placental trophoblast, and antenatal diagnosis can be performed by analysis of merosin expression in chorionic villous samples. Because secondary merosin deficiency occurs in other forms of CMD, great care should be taken when considering this approach in families where no mutation in *LAMA2* has been found.

**125.7.3.6 Animal Model.** The *dy/dy* mouse was studied extensively during the 1960s as a possible model for DMD, but enthusiasm waned when it was shown to also have peripheral nervous system involvement. Merosin is markedly reduced in the dystrophic *dy/dy* mouse. The *dy* locus has been located close to the gene for merosin in the mouse, suggesting that the mouse *dy* mutation is in the merosin gene. The presumed mutation, however, is yet to be identified. A milder allelic mutant of the *dy* mouse (the *dy<sup>2J</sup>/dy<sup>2J</sup>*), whose muscle is merosin-positive, has been shown to have a splice-site mutation within the merosin gene.

#### 125.7.4 Congenital Muscular Dystrophy with Partial Merosin Deficiency

A number of patients with partial merosin deficiency and a documented mutation in the *LAMA2* gene have also been reported. The clinical phenotype is generally less severe than in the form with complete or near-complete merosin deficiency. Unlike the complete form, these patients show delayed walking but independent ambulation. These patients also show white matter changes on MRI, and in some of them, epilepsy has also been

reported. On muscle biopsy, it is the N-terminus of laminin  $\alpha 2$  that is more substantially decreased, whereas the C-terminus can be normal or only mildly decreased. A recent paper comparing patients with absent and partial reduction has reported that compared with the absent merosin group, patients with partial merosin deficiency had later presentation ( $>7$ days) ( $P=0.0073$ ), were less likely to lack independent ambulation ( $P=0.0215$ ), or require enteral feeding ( $P=0.0099$ ) and ventilatory support ( $P=0.035$ ) (268).

#### 125.7.5 Ullrich Congenital Muscular Dystrophy

This form is reported to be one of the most, if not the most common form of CMD, but its prevalence is not yet fully appreciated.

**125.7.5.1 Pathogenesis.** Ullrich CMD results from a defect in collagen type VI. The three collagen VI subunit chains assemble into microfibrils, which form a network that associates with other extracellular matrix proteins. It is thought that collagen VI stabilizes the myofibrils during contraction by anchoring the basement membrane to the interstitial extracellular matrix, and that this function is perturbed in Ullrich CMD (269,270).

**125.7.5.2 Clinical Features.** The typical clinical features are those reported by Ullrich in 1930, when he first described a form of “congenital atonic-sclerotic muscular dystrophy” characterized by contractures of the proximal joints, marked distal laxity, and normal intelligence. Contractures and hypotonia, which are often associated with torticollis and hip dysplasia, are usually present at birth. However, a proportion of children may present with delayed milestones. Maximum functional ability is variable, because some will only achieve assisted ambulation, whereas others will acquire the ability to walk independently. Patients with Ullrich CMD usually develop scoliosis often associated with rigidity of the spine irrespective of whether they have achieved independent ambulation. The laxity of hands and feet is always significant and often associated with proximal contractures that become more marked with time. Failure to thrive and early and marked respiratory involvement are generally obvious by the end of the first decade and become more severe in the second decade, often requiring treatment with noninvasive nocturnal ventilation between the ages of 10 and 15 years (271). On examination, there are associated foot deformities with protrusion of the calcaneum. There is also a tendency to develop skin manifestations such as follicular hyperkeratosis, and in some cases, hypertrophic scars and keloids. Serum CK is normal or only mildly elevated.

**125.7.5.3 Muscle Pathology.** Muscle biopsy can show a variable pathology ranging from myopathic to clearly dystrophic patterns. Collagen VI is generally deficient in muscle and skin on immunofluorescence. However,

although a deficiency of collagen VI is a clear marker of Ullrich CMD, normal collagen VI expression in muscle does not exclude a diagnosis of CMD, and collagen VI status should also be checked on fibroblast cultures. There is some correlation between the extent of reduction in collagen VI in muscle and clinical severity: Patients without collagen VI always have a severe phenotype, whereas patients with a mild collagen VI reduction have a more variable phenotype (272).

**125.7.5.4 Molecular Genetics.** Ullrich CMD can be caused by recessive mutations in the *COL6A1* or *COL6A2* genes on chromosome 21q22, or the *COL6A3* gene on chromosome 2q37 (109,273,274). Heterozygous mutations in the same genes cause the milder allelic condition BM. These genes have 107 cumulative coding exons and frequent polymorphisms, thus mutation analysis is not straightforward. A relatively small number of mutations have been reported, and their mechanisms are still being elucidated (275). Truncating mutations have been reported most commonly and include nonsense and splice-site mutations, as well as small deletions, insertions, or duplications (109,273,274,276,277). These may result in nonsense-mediated mRNA decay and a corresponding reduction in collagen VI or synthesis of abnormal monomers, which form a structurally abnormal microfibrillar network (278). In one patient with a homozygous nonsense mutation in *COL6A3*, the mild clinical phenotype may have been explained by alternative splicing (273). Other mutations in Ullrich CMD are predicted to result in in-frame exonic deletions, and these patients can have classic or mild phenotypes (269,273).

Genetic counseling in Ullrich CMD has been complicated by the recent identification of an increasing number of *de novo* dominant mutations in some patients (279,280). These mutations encode structurally abnormal monomers that have a dominant negative effect on collagen VI microfibrillar assembly. In addition, *de novo* dominant putative mutations in the collagen VI genes have been identified in 10 of a cohort of 26 Ullrich CMD patients, suggesting that *de novo* dominant mutations might account for a significant proportion of Ullrich CMD, although the pathogenicity of these putative mutations is yet unproved (109).

Heterozygous, dominantly acting, mutations in *COL6A1*, *COL6A2*, or *COL6A3* are known to cause BM (270), even though recessive mutations have also been reported (112,113). Some mutations result in haploinsufficiency, whereas others have a dominant negative effect on microfibrillar assembly. Genotype–phenotype correlations are becoming clearer, and with few exceptions, particular mutations are strictly associated with either Ullrich CMD or BM (273). The difference between Ullrich and BM, however, is not always straightforward and a number of phenotypes have clinical findings that are intermediate and not easily classifiable as Ullrich or BM, especially in young children (271,280).

There is definite genetic heterogeneity within Ullrich CMD, although the extent of this is not yet clear. cDNA sequencing excluding mutations in the *COL6* genes in several Ullrich CMD patients with classic clinical phenotypes (including reduced collagen VI immunolabeling in muscle) strongly suggest that mutations in other genes may underlie at least some cases of Ullrich CMD (269).

**125.7.5.5 Genetic Counseling.** Genetic counseling in Ullrich CMD is complicated by the possibility of recessive or *de novo* dominant mutations in Ullrich CMD, the clinical overlap with BM, and the difficulties in mutation analysis of the large *COL6* genes.

The sibling recurrence risk for recessive cases of Ullrich CMD is 25%. The recurrence risk in families in which the index case has a *de novo* dominant mutation will be low and will relate to the (still theoretical) possibility of gonadal mosaicism. Cases with mild Ullrich CMD overlap clinically and pathologically with severe BM cases. As BM is generally, but not always, dominantly inherited and shows variable expression, a parent may be minimally affected, and in this situation, there would be 50% sibling recurrence risk. Careful examination of parents and consideration of muscle biopsy or MRI can be helpful in this regard, but again, a definitive resolution may require molecular genetic testing.

Antenatal diagnosis can be performed by linkage analysis or direct mutation analysis, where there is a molecular diagnosis in the proband. Collagen VI is expressed in the placenta, and its deficiency can be detected by immunolabeling in chorionic villous samples (281). Antenatal diagnosis was reported in a family in which reduced collagen VI immunolabeling was documented in the proband, in combination with molecular testing. Antenatal diagnosis using collagen VI immunolabeling would be possible in families in which the proband has a definitive reduction in collagen VI in muscle. Careful consideration would be recommended before offering this approach without accompanying molecular analysis.

**125.7.5.6 Integrin Alpha 9.** A number of cases with Ullrich CMD-like phenotypes, but with normal collagen VI in muscle and absence of collagen VI subunit mutations have been reported (269,279), suggesting that other disorders may share clinical signs with Ullrich CMD. Mutations in the integrin  $\alpha$ -9 gene have been found in 14 cases from 11 French Canadian families with congenital hypotonia, weakness, contractures, distal joint hyperlaxity, scoliosis, normal intelligence, and delayed motor milestones but with normal collagen 6 on muscle biopsies and no mutations in the *COL6* genes. At variance with Ullrich CMD, they all acquire the ability to walk and do not develop respiratory failure. A genome-wide scan established linkage to a region on chromosome 3p23–21 (282). In the reported cases haplotype analysis defined a 1.6-cM candidate interval, suggesting that two common mutations accounted for 78% of carrier chromosomes and more recently mutations in the *ITGA9* were also reported (283).

**125.7.5.7 Integrin Alpha 7.** Deficiency of integrin  $\alpha 7$ , a basal lamina muscle-specific laminin receptor, has so far been reported in three male children. All three patients had delayed motor milestones and two of the three achieved independent ambulation while the third one had a more severe phenotype. A recent paper reported the progression of clinical signs in these patients with progressive weakness, scoliosis, and respiratory impairment, requiring noninvasive ventilation at the age of 12 years (284).

### 125.7.6 Congenital Muscular Dystrophy with *SEPN1* Mutations and Rigidity of the Spine

This form, characterized by rigid spine, early respiratory failure, and slowly progressive weakness, was first described as a subgroup of CMD. Following the identification of the gene on chromosome 1p35–36, the phenotype has been more clearly defined and expanded, and it has become obvious that this disorder is relatively frequent (285).

**125.7.6.1 Clinical Features.** Mild hypotonia and weakness may be present in the first months of life, but developmental milestones are often normal and patients with CMD with rigidity of the spine develop Achilles tendon contractures and rigid spine in the first years. On examination, there is weakness of the axial muscles and, to a lesser extent, the proximal muscles. Muscle weakness does not increase significantly with age, and patients affected by this form rarely lose the ability to walk independently although their motor abilities may decrease because of the tendency to develop progressive contractures. The spine becomes increasingly rigid with time, and the condition often develops into progressive and severe scoliosis. Progressive respiratory involvement is typically observed in the first decade, and respiratory failure requiring nocturnal ventilatory support is invariable in the second decade of life, when patients are often still ambulant. Serum CK is either normal or minimally elevated. Muscle MRI shows a typical pattern that helps in the differential diagnosis with the other forms of CMD with rigid spine (286).

**125.7.6.2 Muscle Pathology.** Muscle biopsy changes are variable, ranging from minimal myopathic changes to dystrophic (285). There are no specific antibodies to detect possible deficits of selenoprotein N, and immunocytochemistry does not provide additional information.

**125.7.6.3 Molecular Genetics.** CMD with rigidity of the spine results from recessive mutations in the *SEPN1* gene on chromosome 1p36, which encodes an endoplasmic reticulum protein, selenoprotein N (287), a member of the selenoprotein family, so called because the proteins incorporate selenium in the form of selenocysteine. A role for selenium in muscle was suggested a long time ago by the association of selenium deficiency and skeletal and cardiac muscle disease in livestock and the more

recent observation that selenium deficiency in humans is associated with cardiomyopathy. The pathogenesis of this form of CMD remains unclear.

Mutations in *SEPN1* were initially described in families with CMD with rigidity of the spine (287) but have since been identified in another two groups of patients: those with classic multimini core disease [2890] and those with desmin-related myopathy with Mallory body-like inclusions (288). Despite striking overlap in their clinical phenotypes, these patients had previously been considered to have separate disorders on the basis of distinctive pathologic abnormalities demonstrated on muscle biopsy. Now, it is apparent that different histologic changes can coexist in the same patient, if different muscles are examined (285).

The mutations found in *SEPN1*-related myopathies are scattered throughout the gene and can be nonsense, missense, or frameshifting. Mutations in exon 1, encoding a region implicated in ER localization of *SEPN1*, tend to result in more severe phenotypes, but there are no other genotype–phenotype correlations (285). The same deletion has been described in two patients with different pathologic abnormalities. One case was homozygous for the deletion and had typical Mallory bodies, whereas the other was a compound heterozygote, with the deletion on one allele and a second mutation on the other, and did not have Mallory bodies (288).

CMD with rigidity of the spine is also genetically heterogeneous. At least one third of patients with an indistinguishable clinical phenotype do not harbor mutations in *SEPN1* (285). Recently a form with axial muscular dystrophy and other features similar to those found associated with *SEPN1* mutations have been found in patients with a multisystem disorder and mutations in the selenocysteine (Sec) insertion sequence-binding protein 2 (also known as SBP2). These individuals have reduced synthesis of most of the 25 known human selenoproteins, resulting in a more complex phenotype including azoospermia, photosensitivity, and impaired T lymphocyte proliferation and abnormal mononuclear cell cytokine secretion, highlighting the role of selenoproteins in different biological processes (289).

### 125.7.7 Dystroglycanopathies

The term “dystroglycanopathies” has been used to describe a genetically heterogeneous group of muscle disorders, in which the diagnosis is based on the detection of hypoglycosylated  $\alpha$ -dystroglycan by immunolabeling and/or on Western blot on muscle biopsy. The spectrum of dystroglycanopathies ranges from CMD forms with structural brain changes and often eye abnormalities and mental retardation to mild cases of LGMDs with late onset and no brain or eye involvement. In this chapter, we will only report the cases with early onset labeled as CMD.

**125.7.7.1 Pathogenesis.** The dystroglycanopathies result from abnormal glycosylation of the sarcolemmal protein  $\alpha$ -dystroglycan, owing to mutations in genes encoding known or putative glycosyltransferase enzymes (199,201).  $\alpha$ -Dystroglycan is a peripheral membrane glycoprotein that associates tightly with transmembranous  $\beta$ -dystroglycan (290,291). Glycosylated epitopes on  $\alpha$ -dystroglycan bind extracellular matrix ligands, including laminin, perlecan, agrin, and the neuron-specific cell surface proteins neuexins. The cytoplasmic tail of  $\alpha$ -dystroglycan interacts with dystrophin, or its homolog utrophin, which, in turn, binds cytoskeletal actin, thus linking the extracellular matrix to the actin-associated cytoskeleton.

In the dystroglycanopathies, mutations in glycosyltransferase genes are known or proposed to result in reduced activity of the corresponding enzymes (292–294). As a result,  $\alpha$ -dystroglycan is hypoglycosylated and has reduced affinity for its ligands (295–301). In skeletal muscle, this is presumed to disrupt the critical linkage between the extracellular matrix and the intracellular cytoskeleton. Hypoglycosylation of  $\alpha$ -dystroglycan is presumed to play a major role in pathogenesis of the brain malformations in dystroglycanopathy patients, although hypoglycosylation of other proteins could also play a part. In the brain, dystroglycan is expressed at the glia limitans (302). The integrity of the glia limitans is necessary for correct organization of the radial glial cells, which are involved in guiding cortical neurons on their inside-out migration from the periventricular regions to the surface of the brain (303–306). Defects in the glia limitans are observed in patients with dystroglycanopathy and allow migration of postmitotic neurons and glial cells through the pia into the subarachnoid space, giving rise to the cobblestone appearance of the brain surface (300).

**125.7.7.2 Clinical Features.** Dystroglycanopathies are a very complex group of disorders, and while distinct phenotypes had been originally thought to be associated with the involvement of individual genes, the same phenotype has subsequently been reported in association with many of the known genes. Conversely, mutations in individual genes have been associated with different phenotypes. The CMD forms share a considerable clinical, pathologic, and imaging overlap (201,285,306,307), and the involvement of the CNS plays an important role in defining the different phenotypes.

The classification of these forms has changed over the years in order to take into account the heterogeneity of both of phenotypes and genetic defects. While the early studies following the identification of the first genes involved mainly focused on distinct known phenotypes, namely MEB, WW, and Fukuyama, or other phenotypes with normal brain MRI scans, more recent studies have reported that the spectrum of brain lesions also includes a significant number of posterior fossa lesions, such as cerebellar dysplasia or hypoplasia (307,308). A simplified clinical classification system was suggested in a

paper reporting a large series of all dystroglycanopathies, from the CMD, i.e. those with early onset discussed in this chapter, to the LGMDs that have later onset and often a milder phenotype than CMD (306). The CMD spectrum included five forms: WWS, MEB, CMD with cerebellar involvement (CMD CRB), CMD with normal MRI and mental retardation (CMD MR), and CMD with normal MRI and no mental retardation (CMD no MR). A simplified version of this nomenclature has been recently suggested following new OMIM entries. The group of muscular dystrophies with deficit of dystroglycan (MDDG) has been first subdivided into three broad phenotypic groups denoted types A, B and C, each including some of the seven categories proposed by Godfrey et al. (307).

- Type A represents the phenotypes with cortical involvement and the most severe phenotypes: WWS, WWS-like, MEB and Fukuyama congenital muscular dystrophy (FCMD)-like;
- Type B represents cases of CMD with posterior fossa abnormalities or normal MRI: CMD CRB, CMD MR, and CMD no MR,
- Type C represents both LGMD with MR and LGMD with no MR. These are rare causes of LGMD to be considered in patients with reduction of  $\alpha$ -dystroglycan and no mutations in *FKRP*.

#### **125.7.7.2.1 Phenotypes with Cortical Involvement.**

**125.7.7.2.1.1 Fukuyama Congenital Muscular Dystrophy.** FCMD is characterized by muscular dystrophy with mental retardation. It is the second most common form of childhood muscular dystrophy in Japan after DMD, with an incidence of seven to 12/100,000. Onset is extremely early, and many infants present with poor sucking during the neonatal period. Muscle weakness is generalized and involves the facial muscles, giving a typical appearance. Motor milestones are markedly delayed, but most achieve the ability to sit unaided and to crawl on the knees, with the maximal motor ability acquired between the ages of 2 and 8 years. A few patients achieve independent ambulation, but most are unable to walk. With time, however, motor function gradually deteriorates, and contractures become more evident. By the age of 10 years, most of these children become immobile, and the majority dies by their late teens. All cases of FCMD have a high CK, even in the early stages of the disease that tends to decline with age.

##### **125.7.7.2.1.1.1 Clinical Features.**

- CNS involvement

Intellectual retardation is usually severe, with more than one half unable to speak. However, the intelligence quotient varies from 20 to 90 so that, in some cases, intelligence is within the normal range. The patients with better mental function tend to be those with the least motor

disability. There is also a high association with seizures. MRI studies demonstrate abnormal neuronal migration during development, resulting in a distorted cerebral gyral pattern with areas of polymicrogyria, macrogyria, and agyria. White matter changes are also frequent, but sequential MRI studies have demonstrated that the abnormal signal in the white matter is most likely to be due to delayed myelination rather to dysmyelination, as it improves with age.

– Eye involvement

Eye abnormalities occur in approximately 60 to 70% of these patients and are rarely severe, with myopia being the most frequent abnormality. More severe ocular changes, such as optic nerve atrophy, cataract, and retinal detachment, have been reported but are rare.

**125.7.7.2.1.1.2 Muscle Pathology.** The muscle usually shows a marked dystrophic picture. Muscle immunocytochemistry reveals a severe depletion of  $\alpha$ -dystroglycan and a secondary reduction of merosin expression (297).

**125.7.7.2.1.1.3 Molecular Genetics.** FCMD results from recessive mutations in the 10 exon *FCMD* gene, which is located on chromosome 9q13 and encodes a putative glycosyltransferase, Fukutin. There is a founder mutation in the Japanese population, shared by more than 80% of FCMD chromosomes. This retrotransposal insertion of novel tandemly repeated sequences within the 3' untranslated region causes a profound reduction in mRNA levels in patient lymphoblasts, perhaps by altering mRNA stability. Most patients who are homozygous for the founder mutation are mildly or typically affected and have very low levels of Fukutin mRNA. Most compound heterozygotes for the founder mutation and a second missense or nonsense mutation are severely affected and more likely to have severe WWS-like manifestations such as hydrocephalus and microphthalmia. These patients have more moderately reduced mRNA levels. It is suggested that the founder mutation causes reduced levels of a normal Fukutin protein, whereas the other mutations have more severe effects by resulting in structurally abnormal Fukutin.

Two non-Japanese patients with novel, homozygous, nonfounder mutations in *FCMD* have been described (13–314). Both patients had severe phenotypes, indistinguishable from WWS. The mutations in both cases were truncating mutations that would be predicted to lead to complete loss of Fukutin activity, in contrast to mutations causing an FCMD phenotype, which are predicted to result in some residual enzyme activity. This expands the spectrum of phenotypes resulting from FCMD mutations and highlights the need to consider FCMD mutations in non-Japanese patients.

**125.7.7.2.1.2 MEB Disease.** The vast majority of reported patients come from Finland, although there have been reports of affected individuals from other

regions (314). Clinical manifestations include severe mental retardation, muscle weakness, and poor vision.

**125.7.7.2.1.2.1 Clinical Features.**

– Muscle involvement

Most patients with MEB have symptoms by 2 months of age, including severe hypotonia, sucking difficulties, and failure to thrive. Children often have a similar facial appearance, with a large head, prominent forehead, and wide fontanelle. The midface is flat, and the nose and philtrum are short. Patients are severely affected both mentally and physically, but a spectrum of severity is also found. They have a generalized weakness, involving the limbs and trunk. Motor development is extremely delayed, but a small minority eventually achieves ambulation with or without support. Over time, however, motor ability deteriorates, with the lower limbs becoming spastic, with increased reflexes and marked contractures. Overall, the disease appears to be progressive, with patients gradually losing their few acquired skills with time. Survival is variable, but many patients lived into adulthood, with some surviving into the 40s and 50s. The CK is usually grossly elevated but can be normal during the first year of life, with the highest values recorded between the ages of 5 and 15 years of age. With time, the CK levels appear to fall, with no abnormal levels found in patients older than 40 years of age.

– CNS involvement

All patients are mentally retarded, most of them severely, although some achieve limited speech. Epilepsy is a common associated feature, with the majority having generalized seizures, which are usually infrequent and associated with fever. Some patients had frequent seizures in the early childhood, with significant fits in the second decade. The electroencephalogram has always been found to be abnormal after 1 year of age. Hydrocephalus is common, and some patients require shunting. Although there is variability between patients, all basically exhibit features of cobblestone lissencephaly with pachygyria over the frontal, temporal, and parietal regions, and polymicrogyria over the occipital region. Enlarged ventricles, brainstem hypoplasia, and cerebellar hypoplasia are also present in most cases. Patchy white matter changes are occasionally seen, but in contrast to patients with WWS, the patches are not present in every case, nor are they as severe.

– Eye involvement

Ocular involvement is a characteristic feature MEB. The most common findings are severe myopia and retinal hypoplasia. Other abnormalities include congenital and infantile glaucoma, nystagmus, and cataract. Electrophysiologic studies in these patients are extremely interesting. In most cases, the electroretinogram is abnormally low, and the visual-evoked potentials abnormally

high. The combination of low electroretinogram and high visual-evoked potentials is exceptional and a striking feature of this disease.

**125.7.7.2.1.2.2 Muscle Pathology.** The muscle biopsy has a dystrophic picture, with variation in fiber size and an increase in connective tissue and adipose tissue, a reduction of merosin expression, and a severe depletion of  $\alpha$ -dystroglycan.

**125.7.7.2.1.2.3 Molecular Genetics.** MEB is autosomal recessively inherited. Mutations in the 22 exon *POMGnT1* gene, located on chromosome 1q32–34, have been identified in the classic Finnish MEB cases and in a proportion of patients with MEB from other geographical regions (294).

*POMGnT1* encodes the Golgi-resident glycosyltransferase, protein O-linked mannosyl  $\alpha$  1,2-*N*-acetylglucosaminyl transferase 1. *POMGnT1* transfers *N*-acetylglucosamine from UDP-GlcNAc to O-mannosyl glycoproteins. It is implicated in the second step in synthesis of a common tetrasaccharide structure on  $\alpha$ -dystroglycan (Sia  $\alpha$ 2-3Gal $\beta$ 1-4GlcNAc $\beta$ 1-2Man-Ser/Thr) that has been directly implicated in laminin binding.

There is a founder mutation in the Finnish population, specifically a splice-site mutation in intron 17, which is present on 99% of Finnish MEB chromosomes, as well as in patients from other countries who may share a common ancestor (315). Other MEB-causing mutations are scattered through the *POMGnT1* gene. They are mostly either mutations predicted to result in a truncated protein or missense mutations within the catalytic domain (294,315). One study suggested that mutations at the 5' terminus of the *MEB* gene resulted in more severe brain abnormalities than mutations at the 3' terminus (316). However, this correlation was not supported by a subsequent study (315). Those mutations studied, to date, all virtually abolish *POMGnT1* enzyme activity, and this can be assayed in extracts from muscle biopsy samples (293,294,317).

MEB phenotypes have also been reported with mutations in *POMT1* and *POMT2*, *FKRP*, and *LARGE*. These cases were clinically indistinguishable from patients with *POMGnT1* mutations.

*POMT1* encodes an endoplasmic reticulum-resident glycosyltransferase, protein O-mannosyltransferase 1 (295,318). *POMT1* is proposed to catalyze transfer of the initial mannose residue to the tetrasaccharide structure, Sia  $\alpha$ 2-3Gal $\beta$ 1-4GlcNAc $\beta$ 1-2Man-Ser/Thr, on  $\alpha$ -dystroglycan. The *POMT2* gene is homologous to *POMT1* and encodes another mannosyltransferase, *POMT2*. Neither *POMT1* nor *POMT2* is active when expressed alone, suggesting that formation of an active enzyme complex is required for glycosyltransferase activity (318). *FKRP* (Fukutin-related protein), a small gene with a single-coding exon was identified on the basis of its sequence homology with FCMD and, like FCMD, encodes a putative glycosyltransferase whose mode of action is not yet known.

**125.7.7.2.1.3 Walker–Warburg Syndrome.** WWS is a rare form of CMD, presenting with the triad of eye and brain malformations and muscular dystrophy. It has been reported in patients from many different nationalities and races.

**125.7.7.2.1.3.1 Clinical Features.** WWS has the most severe phenotype of the MEB syndromes, and the condition is usually associated with early death.

#### – Muscle involvement

In pregnancy, mothers usually notice decreased fetal movements, often complicated by polyhydramnios. As a result of marked hydrocephalus causing cephalopelvic disproportion, delivery is often by caesarean section. Commonly, resuscitation is required at birth, and a significant majority of them are still born or die in the perinatal period. On reviewing the survival data, median survival time for all liveborn infants was 18 weeks, although about 5–10% survived more than 5 years. The longer survivors usually were less severely mentally retarded. Of the survivors, most have profound mental and motor retardation, but as with the other syndromes, there is a spectrum of severity, and some of the less affected eventually acquire the ability to sit and roll. The CK level is usually elevated but actual values can vary tremendously between patients and in individual patients over time. Patients with normal values have been recorded, but they were either infants or children older than 10 years.

#### – CNS involvement

As suggested by the extremely severe phenotype, full expression of cobblestone lissencephaly is usually observed in this syndrome. Most affected children have severe gyral changes, with agyria and additional areas of macrogyria and polymicrogyria. The leptomeninges are thick and can obliterate the interhemispheric fissure and subarachnoid space. The cortex is abnormally thick; frequently, the corpus callosum and septum pellucidum are absent or hypoplastic. Microscopically, the cortex is severely disrupted with no recognizable neuronal layers. Unlike the other syndromes, the white matter is extensively involved with diffuse changes throughout the cortex. Ventricular dilation, with or without progressive hydrocephalus, is extremely common and, at one time, was a required diagnostic criterion. In addition, some patients have been found to have congenital microcephaly. Cerebellar malformation is seen in all patients. The cerebellum is hypoplastic, particularly the posterior vermis, and the gyral pattern is abnormal. EM shows that the neuronal layers are severely disrupted. In some patients, hypoplasia of the vermis is associated with enlargement of the fourth ventricle, the Dandy–Walker malformation. Seizures are common in these patients and can be difficult to control.

#### – Eye involvement

Patients with WWS show a wide spectrum of eye abnormalities, with abnormal differentiation of the

retina being also described. The spectrum of retinal involvement varies, ranging from severe to mild. Severe abnormalities include microphthalmia, colobomatous malformation, and retinal detachment secondary to retinal dysplasia. Milder changes include abnormal retinal vascularization, absent macular and optic disc hypoplasia. Anterior chamber malformations can also be found in some patients; common abnormalities including corneal clouding and narrowing of the iridocorneal angle, with or without glaucoma and cataract.

**125.7.7.2.1.3.2 Muscle Pathology.** Muscle biopsy is dystrophic, but there have been reports of normal muscle biopsies in affected infants during the first months of life, and it has been suggested that the biopsy becomes more dystrophic with time. Muscle involvement may not always be uniform, and multiple biopsies from individual patients have shown variability in the degree of dystrophic changes. Immunocytochemistry shows a reduction of merosin expression and a severe depletion of  $\alpha$ -dystroglycan (295,319).

**125.7.7.2.1.3.3 Molecular Genetics.** WWS is a highly genetically heterogeneous disorder. Autosomal recessive mutations in four different genes have been identified so far, which result in indistinguishable clinical phenotypes. These genes explain only a minority of cases (138), and genome wide linkage studies predict a minimum of 10 loci (285). The first gene found to cause WWS was *POMT1* (295,318), mutated in up to 20% of WWS cases (295,320). The mutations in *POMT1* reported in WWS are either nonsense mutations, single-base pair insertions, or missense mutations scattered throughout the gene. The nonsense mutations are predicted to encode nonfunctional proteins. The other reported mutations in *POMT1* have been demonstrated to abolish its mannosyltransferase activity, thus, presumably, resulting in hypoglycosylation of  $\alpha$ -dystroglycan (292). WWS phenotype has subsequently been also found in patients with mutations in *POMT2* (306,307,321). Two patients were homozygous for mutations predicted to result in truncated proteins, while the other patient was homozygous for a splice site mutation. WWS phenotype has also been found in association with mutations in the *FCMD* or *FKRP* genes (313,314,322), again highlighting the overlapping phenotypes that result from mutations in glycosyltransferase genes.

#### **125.7.7.2.2 Dystroglycanopathies with Posterior Fossa Abnormalities or Normal MRI.**

**125.7.7.2.2.1 Clinical and Imaging Findings.** A number of patients with CMD and  $\alpha$ -dystroglycan deficiency have been found with posterior fossa abnormalities. The cerebellum is more often involved, in isolation with signs of hypoplasia or dysplasia (cerebellar cysts) or in combination with brainstem and pons abnormalities. Cerebellar involvement is generally associated with mental retardation and often with microcephaly (307,308). Patients with normal brain MRI can also have microcephaly and mental retardation (306), but a proportion of

them will have normal head circumference and no mental retardation. This group was originally described by Brockington et al. (323) and has been labeled as MDC1C according to the old nomenclature. Patients affected by both forms with and without mental retardation generally show hypotonia and feeding difficulties at birth and markedly delayed motor milestones. They usually achieve the ability to sit but do not achieve independent ambulation. On examination, there is a generalized hypertrophy of the lower limb muscles with wasting of the shoulder girdle and a peculiar posture of the arms, with cubital pronation of the forearm and partial flexion of the fingers. Weakness is more marked in the arm than in the legs. Feeding difficulties may persist after the neonatal period, and gastrostomy may be required, especially if aspiration is detected on videofluoroscopy. They often develop respiratory failure and echocardiography evidence of left ventricular dilatation in the second decade of life.

**125.7.7.2.2.2 Molecular Genetics.** Cerebellar cysts are more often found in patients with *FKRP* and *POMGnT1* mutations but have also been reported in association with *POMT1* and *POMT2* mutations. Cerebellar hypoplasia and microcephaly in contrast are generally associated with *POMT1* and *POMT2*. Patients with normal brain MRI but with microcephaly and mental retardation are more often related to mutations. The form with normal brain MRI and no mental retardation generally results from autosomal recessive mutations in *FKRP*.

**125.7.7.3 Dystroglycanopathies: Genetic Overview.** The spectrum of phenotypes associated with mutations in the individual genes responsible for dystroglycanopathies expands beyond the CMD cases, and some of the known genes cover a broad range of phenotypes. *FKRP* is the best example of the wide heterogeneity of phenotypes. Shortly after the initial description of MDC1C, mutations in *FKRP* were found to underlie a common form of LGMD, LGMD2I (197). In MDC1C and LGMD2I, a correlation has been shown between the immunohistochemical reduction in  $\alpha$ -dystroglycan, the mutation, and the clinical phenotype (296). In MDC1C, there is severe depletion of  $\alpha$ -dystroglycan, and patients are either compound heterozygotes for one missense and one nonsense mutation, or homozygous for a missense mutation. Compound heterozygosity for two null alleles has not yet been reported in *FKRP*, suggesting that a total absence of enzyme activity may result in embryonic lethality. Patients with severe LGMD2I, who have a DMD-like course, show a significant, but lesser, depletion of  $\alpha$ -dystroglycan and are compound heterozygotes for a missense mutation, L276I and another, variable, second mutation. Patients at the milder end of the LGMD2I spectrum show a variable but subtler depletion of  $\alpha$ -dystroglycan and are either L276I heterozygotes or, more commonly, homozygotes. *FKRP* mutations have subsequently also been found in patients with cerebellar cysts, MEB, and in WWS patients (295,306,307). Mutations have been described scattered throughout the

coding sequence of *FKRP* although not yet in the transmembrane region (197,202,323,324). Those mutations causing brain involvement are not located in a different *FKRP* domain compared with other reported mutations (295,325). The cerebellar cyst and WWS patients were homozygous for novel, missense mutations. The most likely explanation for the brain involvement in some patients with *FKRP* mutations is that such mutations reduce enzyme activity below a certain threshold that is required for normal brain development. In support of such a hypothesis, the patients with cerebellar cysts and MEB, in whom skeletal muscle was available for study, showed a virtual absence of glycosylated  $\alpha$ -dystroglycan (Voit and Muntoni, personal communication) and references (321,326).

The spectrum of phenotypes resulting from mutations in *FKRP* is the broadest of all the glycosyltransferase genes to date, but *POMT1* and *POMT2* mutations have also been associated with a similar spectrum of phenotypes from WWS and MEB to milder LGMD phenotypes. *POMGnT1* in contrast is more often associated with MEB and cerebellar cysts phenotypes, and so far, less phenotypic heterogeneity has been reported. *LARGE* mutations are much less common and so far have been reported in a case with white matter changes and in WW phenotype.

Although it may be possible to prioritize testing based on clinical phenotype, the phenotypic overlap means that it is necessary to test all known genes in all patients with dystroglycanopathy. It is also important to highlight that approximately 50% of the patients with CMD and  $\alpha$ -dystroglycan deficiency do not show mutations in the known genes, suggesting further genetic heterogeneity.

### 125.7.8 Other Forms of CMD due to Glycosylation Disorders

While until recently it has been assumed that all the forms with muscle involvement were dystroglycanopathies due to O-glycosylation defects, in the last year there has been increasing evidence that muscle may also be involved in patients with N-glycosylation defects, well known to be responsible for congenital disorders of glycosylations. A recent paper has reported a homozygous missense mutation in *DPM3*, in a patient with mild muscular dystrophy, dilated cardiomyopathy and stroke-like episodes with no brain involvement, and a reduction in Dol-P-Man synthase activity on fibroblasts. Mutations in *DPM2* have also been identified in two siblings with muscular dystrophy, severe mental retardation, microcephaly, myoclonic epilepsy, and cerebellar hypoplasia on brain MRI (312,327).

### 125.7.9 Congenital Muscular Dystrophy Type 1B

This autosomal recessive form of muscular dystrophy, presenting with proximal girdle weakness, generalized muscle hypertrophy, rigidity of the spine, and

contractures of the Achilles tendon, with grossly elevated serum CK, was originally described in a consanguineous family from the United Arab Emirates. Early respiratory failure was a feature in these patients. There is secondary merosin deficiency and  $\alpha$ -dystroglycan deficiency in skeletal muscle (201). MDC1B has been mapped to chromosome 1q42.

### 125.7.10 Congenital Muscular Dystrophy Type 1D

Mutations in the 16-exon *LARGE* gene, located on chromosome 22q12.3-13.1, and encoding a putative glycosyltransferase, have been identified in one patient from the United Kingdom (328). This gene was analyzed because it is mutated in the *myd LARGE* mouse, a model of muscular dystrophy in which  $\alpha$ -dystroglycan is abnormally glycosylated (329). The patient was a compound heterozygote; she had a missense mutation affecting a highly conserved residue in a putative catalytic domain, together with a 1-bp insertion, predicted to encode a truncated protein lacking part of a putative catalytic domain. The patient muscle showed milder hypoglycosylation of  $\alpha$ -dystroglycan than the *myd LARGE* mouse. This may be explained by residual *LARGE* activity in the patient, in contrast with the *myd LARGE* mouse, which has a homozygous out-of-frame mutation predicted to encode a nonfunctional protein. Interestingly, the patient had a neuronal migration defect and electroretinographic abnormalities that were also similar to those seen in the *myd LARGE* mouse.

### 125.7.11 Other Dystroglycanopathies

**125.7.11.1 Microcephaly-Normal Structural Brain.** Another form of CMD with mental retardation but normal brain MRI was reported in two siblings who never achieved independent ambulation. Laminin  $\alpha$ -2 and  $\alpha$ -dystroglycan were reduced in the muscle biopsy.

**125.7.11.2 Microcephaly-Pachygyria-Peripheral Neuropathy.** Four siblings in one family have been described with generalized muscular wasting and weakness, calf pseudohypertrophy and joint contractures, microcephaly, and severely delayed psychomotor development. There was pontocerebellar hypoplasia, bilateral opercular abnormalities, and focal cortical dysplasia on brain MRI. One patient showed electrophysiologic evidence of demyelinating peripheral neuropathy. Laminin  $\alpha$ -2 expression was normal but  $\alpha$ -dystroglycan was virtually absent (319).

### 125.7.12 LMNA-Related Congenital Muscular Dystrophy and Infantile Onset Inflammatory Myopathy

*De novo* heterozygous mutations in the *LMNA* gene have recently been described in rare patients with infantile onset, showing a phenotype characterized by severe

muscle weaknesses in the first year of life (330). Most of the patients showed a classic “dropped-head” syndrome phenotype. The weakness appears to be selective, with wasting of the cervicoaxial muscles, associated with rigid spine and proximal involvement in upper limbs and distal in lower. Later onset of proximal limb contractures, ventilatory support, cardiac arrhythmias were also observed in many patients. Muscle appeared dystrophic with inflammatory markers. This new phenotype, now called LMNA-related CMD (L-CMD) and overlaps with the other striated muscle laminopathies, in particular EDMD, because of the humeroperoneal distribution of limb weakness, but the early onset, the head drop, absence of elbow contractures, and rapidly progressive respiratory insufficiency can help to distinguish L-CMD. The specific *LMNA* mutation found in these patients is currently considered as the major cause of the severity of this phenotype, although one of the mutations was also reported in association with a milder phenotype, suggesting, again, the possible involvement of other genetic modifying factors, as for EDMD and LGMD1B. Following this first report, *LMNA* mutations were also found in patients showing inflammatory myopathy with infantile onset, with presence of perivascular cuffing and/or endomysial/perimysial lymphocyte infiltration. Joint contractures and cardiac involvement developed later in life (331). These findings further broaden the phenotypic spectrum of laminopathies.

### 125.7.13 Other Forms of Congenital Muscular Dystrophy

Apart from the forms described, in which the primary genetic defect has been identified, there are a number of forms with distinctive phenotypes in which the underlying genetic or protein defect has not yet been identified:

**125.7.13.1 Congenital Muscular Dystrophy with Cataracts.** This form of muscular dystrophy is characterized by mild mental retardation, bilateral cataracts, and normal cranial magnetic resonance imaging

**125.7.13.2 Congenital Muscular Dystrophy with Short Stature, Mental Retardation, and Distal Laxity.** We recently described a form with distal laxity, early respiratory impairment, and a significant overlap with Ullrich CMD but associated with short stature and mental retardation. Linkage to the collagen VI genes was excluded (328).

### 125.7.14 Making a Diagnosis in Congenital Muscular Dystrophy: Practice and Pitfalls

Reaching a correct diagnosis in a patient with CMD requires a combination of careful history taking, clinical examination, selected investigations, and interpretation of the muscle biopsy. Only then can targeted mutation analysis be employed, to confirm the clinical diagnosis and allow genetic counseling.

A thorough clinical history is essential. Although CMD is defined as having an onset in the first 6 months of life, patients may present at a later age, and parents may not recall mild early signs, unless questioned specifically. A detailed family history should be taken, including questions about consanguinity, neonatal deaths, and similarly affected relatives. It is important to ask about mild symptoms in the parents, because several dominantly inherited disorders are included in the differential diagnosis of CMD. Clinical examination may give clues to a particular subtype. The skin changes and joint hypermobility in Ullrich CMD can lead to milder patients being misdiagnosed with benign hypermobility or Ehlers–Danlos syndrome if a systematic search for joint contractures and mild muscle weakness is not made. Patients with RSMD1 can have minimal limb weakness, and so it is important to assess axial muscle power, which is more affected in these patients.

Investigations should always include serum CK, which is a useful guide to likely differential diagnoses. The CK level allows particular disorders to be excluded; for example, patients with merosin deficiency or a dystroglycanopathy will rarely have a CK below 1000 IU/L. Nerve conduction should be measured because this is usually abnormal in merosin-deficient patients, and an alternative diagnosis should be considered in patients with normal nerve conduction. Brain MRI should be performed if merosin-deficient CMD is suspected, looking for the characteristic white matter changes. MRI should also be considered in suspected dystroglycanopathy patients, who may have structural brain abnormalities that may help direct genetic testing. Similarly, detailed ophthalmologic assessment should be performed in suspected dystroglycanopathy patients. Muscle MRI shows a characteristic pattern of muscle involvement in RSMD1 and Ullrich CMD. MRI may also be helpful when considering other differential diagnoses; for example, patients with some congenital myopathies show a characteristic pattern of muscle involvement.

Muscle histology usually shows dystrophic changes in CMD; however, muscle in RSMD1 may show only myopathic changes. Patients with a congenital myopathy due to mutations in the ryanodine receptor 1 gene (*RYR1*) are not infrequently misdiagnosed as having CMD, particularly Ullrich CMD, because both disorders involve distal laxity. A diagnosis of RSMD1 or *RYR1*-associated myopathy should be considered in patients with corelike areas on muscle biopsy. The presence of frequent internal nuclei is another pointer to an *RYR1*-associated myopathy. Another possible misdiagnosis is in patients with dystroglycanopathies, who can have an inflammatory infiltrate and upregulation of HLA in muscle, and may be wrongly diagnosed with an inflammatory myopathy. Immunolabeling of muscle allows the diagnosis of specific CMD subtypes; however, this analysis is not always straightforward. Immunohistochemical changes may be subtle in partial merosin deficiency, and antibodies to both the 80-kD and 300-kD fragments of

merosin should be used to avoid missing minor abnormalities. It should also be noted that secondary merosin deficiency could occur in the dystroglycanopathies. Although immunolabeling of collagen VI is reduced in Ullrich CMD, this reduction can be mild and difficult to appreciate, and the diagnosis could be missed in such cases.

In conclusion, the diagnosis of CMD requires substantial clinical expertise and specialized histopathologic techniques. Referral to a specialist neuromuscular center is helpful in reaching a diagnosis in difficult cases.

## 125.8 CONCLUSIONS

The muscular dystrophies represent a widely variable and heterogeneous group clinically (with onset from infancy to late adult life), genetically, and at the level of the underlying protein defect. Precise diagnosis can be sought in the majority of cases. Precise diagnosis can be used to help predict prognosis and plan supportive therapies, which are proven to influence longevity and quality of life. Current diagnostic strategies rely on a combination of review of clinical symptomatology, MRI studies, muscle biopsy analysis (especially immunolabeling techniques), and direct mutation testing. Current novel technologies will most likely elucidate new causes for muscular dystrophies, new diagnostic algorithms, and the hope is that they will also provide routes for specific therapies.

### Biographies

**Anna Sarkozy** Specialty Doctor in Neuromuscular Genetics at the Northern Genetic Service, in Newcastle upon Tyne, UK. Dr Sarkozy is a Clinical Geneticist with a PhD in Medical Genetics, currently working with Prof Bushby for the National Specialised Commissioning Team (NSCT) for rare neuromuscular diseases in Newcastle upon Tyne, UK, with a special interest in limb-girdle muscular dystrophies and related disorders.

**Kate Bushby** Professor of Neuromuscular Genetics and the Newcastle University in Newcastle upon Tyne, UK and member of the Neuromuscular Research Group within the Institute of Genetic Medicine with leading role in the National Specialised Commissioning Team (NSCT) for rare neuromuscular diseases. Prof Bushby is the coordinator of the EUCERD Joint Action on Rare Diseases, and is former joint coordinator of the FP6 TREAT-NMD Network of Excellence; she is also Deputy Director of the MRC Centre for Neuromuscular Diseases. Prof. Bushby has a long-standing interest in the molecular genetics of the limb-girdle muscular dystrophies and related disorders and is interested in the best possible development and implementation of care guidelines as well as clinical trials.

**Eugenio Mercuri** Professor in Pediatric Neurology at the Catholic University, in Rome, Italy. Prof Mercuri is Head of the Pediatric Neuromuscular unit and coordinator of the Congenital Muscular dystrophy (CMD) Network in Italy. His areas of expertise are congenital muscular dystrophy, outcome measures and assessment tools in neuromuscular disorders.

### 126.1 INTRODUCTION

Hereditary motor and sensory neuropathies (HMSNs) are a group of clinically and genetically heterogeneous disorders primarily affecting the PNS. The diagnosis is based on the presence of lower motor neuron signs and evidence of sensory involvement. If lower motor neuron signs are present with normal sensory system, the diagnosis of peripheral motor neuropathy or lower motor neuron disease is likely. Sensory neuropathies in the absence of lower motor neuron signs, and usually associated with autonomic dysfunction are the hereditary sensory and autonomic neuropathies (HSANs), discussed in another chapter. Peripheral neuropathy is frequently part of complex neurologic or multisystemic disorders. In these patients, there is striking evidence of other system involvement, and these disease entities are discussed in other chapters.

### 126.2 HEREDITARY MOTOR AND SENSORY NEUROPATHIES

HMSNs, or Charcot–Marie–Tooth (CMT) disease and related neuropathies, represent a heterogeneous group of hereditary disorders (1–6) of the PNS with an estimated frequency of 1 in 2500 individuals (7). CMT is characterized by slowly progressive, length-dependent neuropathy, manifesting as distal weakness of the legs progressing proximally, followed, in some cases, by hand involvement. Based on motor nerve conduction velocities (NCVs), two major types can be distinguished—type 1 or the demyelinating (CMT1) form (note: refers to all demyelinating forms independent of inheritance pattern), which is characterized by symmetrically slowed NCV

(usually <38 m/s; normal is >45 m/s), and type 2 or the axonal (CMT2) (all axonal independent of inheritance pattern) form, associated with normal or subnormal NCVs and reduced compound muscle action potential (8). Pathologic studies of patients with myelinopathies show segmental demyelination and remyelination, that is, the so-called onion bulb formation (9), whereas studies of patients with axonopathies show normal myelin but fewer nerve fibers. Both CMT1 and CMT2 can be inherited as either an autosomal dominant (AD), autosomal recessive (AR), or X-linked (XL) trait, but often present as sporadic neuropathy (Figure 126-1).

The disease spectrum of both CMT1 and CMT2 is a continuum, often in the same family extending from severe infantile-onset disease to mild adult-onset disease (2). Traditional clinical classifications also include Dejerine–Sottas neuropathy (DSN) and congenital hypomyelinating neuropathy (CHN) (10–14). By definition, the diagnosis of DSN requires the presence of developmental delay, indicating very early onset. The clinical definition of CHN overlaps with DSN, the terminology indicating congenital onset. However, symptoms are frequently recognized as developmental delay in this group of patients also. The distinction between DSN and CHN thus requires a pathologic diagnosis, the presence of onion bulbs in DSN indicating episodes of demyelination and remyelination (12,14–16).

During the previous two decades, an enormous amount of information regarding peripheral nerve function and dysfunction has been obtained through the identification of genes responsible for disease in patients, manifesting inherited peripheral neuropathies, generating a complex

**FIGURE 126-1** Genetics of CMT neuropathy. This figure depicts the delineation of the CMT phenotype into primarily myelin versus axon involvement, the modes of inheritance that can be observed, and the 40 different linked genetic loci. For 34 of these loci, specific genes have been identified and are shown below. Note that, at some of the loci, either dominant or recessive inheritance may be observed depending on the specific mutation. Also, mutations in *GJB1*, encoding the gap junction protein connexin-32, can present as either an axonal or demyelinating neuropathy, or have features of both. In other genes, specific mutant alleles can cause either a CMT1 or CMT2 phenotype.

classification based on the locus or gene involved (Table 126-1). In some instances, mutations in the same genes can cause both demyelinating and axonal neuropathy; the same mutations can have variable disease onset even in the same family, and the inheritance pattern can vary whether the same gene has a dominant negative or a loss of function mutation (17). Thus, this classification will need revision in the future. In this text, CMT1 and CMT2 refer to demyelinating and axonal CMT, respectively, independent of inheritance pattern. Some of these genes or mutations contribute to a significant fraction of inherited peripheral neuropathy cases and, thus, molecular analysis can play a substantial role in establishing a precise and accurate etiological diagnosis, whereas other genes may be involved in only a small minority of patients. This chapter expands upon and updates our previous one (1).

### 126.3 DISEASES PHENOTYPES

#### 126.3.1 Charcot–Marie–Tooth Disease (MIM 118200, 118220)

Clinical symptoms most frequently appear in the first or second decade of life, including tripping, followed by difficulties with heel walking. Weakness of the peroneal muscles impairs foot dorsiflexion and eversion during gait, for which patients compensate by flexing the hip and knee with each step, producing the steppage gait. To achieve better foot stroke patients flex their toes, which with time

becomes rigid (hammer toes). Foot deformities such as pes cavus and heel varus occur late. In most cases, weakness and wasting of the intrinsic hand muscles occurs late in the course of the disease but is not usually related to the degree of leg weakness or atrophy and is also not related to the age of the patient. The thumb lies flat in the plane of the hand instead of opposing the other fingers, giving the appearance of claw hand. Decreased or absent ankle reflexes are virtually universal, and most patients are areflexic. Mild sensory loss can be detected in approximately 70% of the cases. Patients rarely lose the ability to ambulate. Slow NCVs, as seen in the demyelinating form or CMT1, differentiate this form from the axonal or neuronal type or CMT2, in which the NCVs are normal or slightly slow, with reduced amplitudes. Approximately 60–70% of patients have CMT1, whereas about 20–40% are diagnosed with CMT2. Restless leg syndrome occurs in nearly 40% of CMT2 patients (18) but is rare in CMT1 cases. Pathologic studies of patients with myelinopathies show segmental demyelination and myelin sheath hypertrophy, that is, the so-called onion bulb formation, whereas studies of patients with axonopathies show normal myelin but fewer nerve fibers (9,19).

#### 126.3.2 Hereditary Neuropathy with Liability to Pressure Palsies (MIM 162500)

The clinical phenotype of hereditary neuropathy with liability to pressure palsies (HNPP) is characterized by

**TABLE 126-1 Genetic Classification of Charcot–Marie–Tooth Disease and Related Peripheral Neuropathies**

CMT	Locus	Gene	Product	OMIM
CMT1A	17p11.2	<i>PMP22</i>	Peripheral myelin protein 22	118220
CMT1B	1q22	<i>MPZ</i>	Myelin protein zero	118200
CMT1C	16p13.1-p12.3	<i>LITAF</i>	Lipopolysaccharide-induced TNF factor	601098

DI-CMTC	1p34	<i>YARS</i>	Tyrosyl-tRNA synthetase	608323
DI-CMTD	1q22	<i>MPZ</i>	Myelin protein zero	607791
CMTX1	Xq13.1	<i>GJB1</i>	Gap junction beta-1 protein, Connexin 32	302800
CMTX2	Xp22.2	Unknown	Unknown	302801
CMTX3	Xq26	Unknown	Unknown	302802
CMTX4	Xq24-q26.1	<i>NAMSD</i>	Neuropathy, axonal, motor sensory, deafness	310490
CMTX5	Xq21.32-q24	<i>PRPS1</i>	Phosphoribosyl pyrophosphate synthetase 1	311070

recurrent episodes of nerve palsies at compression sites (20,21). The symptoms are transient numbness or weakness lasting hours to weeks. Approximately 64–78% of patients present with acute painless mononeuropathy or brachial plexopathy (22). After multiple attacks, the recovery may be incomplete owing to permanent nerve damage. The repeated demyelination and remyelination result in sausage-like thickening of the myelin sheath (tomacula) (23). The neurologic impairment is usually milder than in CMT1 but can become similar after the fifth decade. Electrophysiologic findings include conduction blocks and mildly slow motor conduction velocities during exacerbations (23).

### 126.3.3 Dejerine–Sottas Neuropathy (MIM 145900)

DSN was originally described as an interstitial hypertrophic neuropathy of infancy. The patients present with motor developmental delay, hypotonia, and areflexia (24,25). Many patients walk eventually, although walking is often delayed beyond the second year. Probably because of proprioceptive deficits, all patients have ataxia and abnormal coordination. Virtually all patients are areflexic. Beginning with the distal musculature of the lower extremities, patients develop progressive muscular atrophy and weakness. By the second decade of life, nearly all

patients have developed proximal weakness in addition to distal weakness and moderate to severe sensory deficits. Although some deteriorate over the first two decades of life and may eventually die from respiratory complications, others have a relatively mild disease course except for progression of limb deformities and scoliosis (25,26). NCVs show marked slowing (<6 to 12 m/s) in a uniform pattern affecting all nerves and nerve segments (24,25). The hypertrophic superficial nerves may be visible and palpable. Patients with DSN have the neuropathologic features of both de/remyelination (onion bulb) and hypomyelination (thin myelin sheets) (15,25).

### 126.3.4 Congenital Hypomyelinating Neuropathy (MIM 605253)

CHN is the most severe form of the HMSNs. The clinical features are present at birth with marked hypotonia, areflexia, and distal muscle weakness (10–14). In some cases, decreased fetal movements and arthrogryposis multiplex congenita have been described (10,14). The NCVs are usually less than 6 to 12 m/s. Clinical distinction between CHN and DSN is often difficult, because frequently the first measurable clinical sign is motor development delay. The diagnosis of CHN is established by nerve biopsy showing hypomyelination, with only a few thin myelin lamellas left without active myelin breakdown products and early onion bulb formations.

### 126.3.5 Roussy–Lévy Syndrome (RLS, MIM 180800)

Roussy–Lévy syndrome (RLS) combines the CMT1 phenotype with marked tremor and sensory ataxia (6,27). Symptoms include early pes cavus, distal leg muscle weakness and atrophy, distal sensory loss, and gait ataxia. As the full phenotypic spectrum of CMT has been defined, however, tremor and sensory ataxia have been clearly identified as common although variable features of CMT (28,29). Therefore, although initially considered a *forme fruste* of Friedreich ataxia, RLS is a CMT variant. Genetic testing confirms this clinical impression. The original family described by Roussy and Lévy segregates an *MPZ* mutation (30), and RLS has also been associated with the *PMP22* duplication and point mutations in *GJB1* (31–33). RLS has never been associated with mutations in *FRDA*, the gene associated with Friedreich ataxia.

## 126.4 DISTAL SYMMETRIC POLYNEUROPATHY—EVIDENCE-BASED MEDICAL GUIDELINES

In 2009, the American Academy of Neurology, American Association of Neuromuscular and Electrodiagnostic Medicine and American Academy of Physical Medicine and Rehabilitation issued a joint practice parameter that provided evidence based recommendations for the role of

laboratory and genetic studies in the process of evaluation of distal symmetric polyneuropathy (DSP). The panel of specialists reviewed available literature devoted to evaluation of polyneuropathy published during the years 1980–2007 and recommended genetic testing to be considered in patients with DSP or an hereditary neuropathy phenotype. According to the guidelines, clinical presentation, mode of inheritance, and electrophysiological findings should be used to guide molecular testing (34,35).

## 126.5 MODES OF INHERITANCE

CMT and related neuropathies exhibit all forms of Mendelian inheritance—AD, AR, and XL. AD-CMT1 is the most frequent pattern observed (2). Forty linked loci (20 AD, 15 AR, and 5 XL; although rarely some mutations in a gene isolated as a dominant locus may behave as a recessive allele in a given family) and 34 CMT-associated genes have been identified (see Figure 126-1 and Table 126-1). HNPP and RLS show AD inheritance, whereas CHN is AR or sporadic. DSN shows both AD and AR forms. Sporadic disease is often a result of new mutation, and thus, the absence of a family history does not preclude molecular genetic testing.

## 126.6 GENETICS

Mutations in genes encoding proteins required for proper development, maintenance, or function of the peripheral nerve may result in neuropathy. Several of the disease genes initially identified encode (i) structural proteins that are important in myelination (e.g. *PMP22*, *MPZ*), (ii) proteins involved with radial transport through the myelin membrane sheath (e.g. *Cx32*), (iii) proteins involved with axonal transport (e.g. *NEFL*, *GAN1*), (iv) transcription factors associated with onset of myelination (*EGR2*, *SOX10*), (v) members of signal transduction pathways (e.g. *PRX*, *MTMR2*, *SBF2*, *NDGR1*), (vi) mitochondrial function-related proteins (e.g. *MFN2*, *GDAP1*), (vii) endosome-related proteins/endocytic recycling (*RAB7*, *SH3TC2*, *FIG4*, *SIMPLE*) and (viii) chaperones (*HSP22*, *HSP27*), (ix) a gene involved in DNA single-strand-break repair (*TDP1*), (x) protein synthesis (*GARS*, *KARS*, *AARS*, *HARS*, *YARS*), and (xi) other genes (e.g. *LMNA*, *KCC3*, *DNM2*) whose peripheral nerve specific functions are less clearly established.

### 126.6.1 Genes Associated with Peripheral Nerve Structure

**126.6.1.1 Peripheral Myelin Protein 22.** The first molecular event discovered, responsible for the majority of CMT, was the duplication of the chromosomal segment harboring *PMP22* (2,36). This discovery introduced a novel molecular mechanism in human mutagenesis, nonallelic homologous recombination (Figure 126-2) and defined a new group of disorders, the genomic disorders

**FIGURE 126-2** Reciprocal recombination resulting in duplication causing Charcot-Marie-Tooth disease type 1A (CMT1A) or deletion associated with hereditary neuropathy with liability to pressure palsies (HNPP). Proximal CMT1A-REP is depicted by a dotted box, distal CMT1A-REP is depicted by a hatched box, and the *PMP22* gene-encoding peripheral myelin protein depicted by a gray box. A, B, C, D, and A', B', C', D' represent unique sequences flanking the CMT1A-REP low-copy repeats on each of the two chromosome homologs, respectively. Gray lines depict the site of crossover and the resulting rearrangements are labeled ABCB'C'D' for the CMT1A duplication and A'D for the reciprocal HNPP deletion. The JCT refers to specific junction fragments detected by probes that are used in diagnostics (PFGE). Homologous meiotic recombination between nonallelic copies of CMT1A-REP's leads to either the CMT1A duplication or HNPP deletion. The CMT1A duplication results in three copies (two on the duplicated chromosome and one on the normal homolog) of the dosage-sensitive *PMP22* gene.

(37,38,230). The reciprocal molecular event, deletion of the same fragment, was predicted and found in HNPP (39,40). This molecular mechanism and the diseases provided substantial evidence for the presence of dosage-sensitive genes in the human genome. Peripheral myelin protein 22 (*PMP22*) is an integral membrane protein of 160 amino acids with four transmembrane domains. The function of *PMP22* is still unknown; however, recent evidence shows that *PMP22* and P0 are involved in both transhomophilic and transheterophilic interactions in cell culture-based assay systems using retrovirally transduced HeLa cells (41). An extra copy of *PMP22*, due to the CMT1A duplication, is associated with CMT1 (2,42,43), and this single molecular event accounts for 70% of families with dominant CMT1 (44,45) and 76–90% of sporadic CMT1 (44,46). The CMT1A duplication is also associated with neuropathy in patients manifesting wide variations in clinical phenotypes such as DSN, RLS, calf hypertrophy, and scapuloperoneal atrophy or Davidenkow syndrome (2). Deletion of *PMP22* leads to HNPP (40). In one study (47), 50% of patients diagnosed with a multifocal neuropathy had the 17p11.2 deletion associated with HNPP. Thus, *PMP22* is a dosage-sensitive gene that, when duplicated or deleted, gives rise to demyelinating neuropathies. Point mutations in *PMP22* have been seen in CMT1, DSN, and CHN phenotypes (43,48,49). As anticipated, loss of function mutations (50), including frameshift, nonsense, and splice-site mutant alleles, result in HNPP, because like the HNPP deletion, they effectively result in *PMP22* haploinsufficiency. Most of the missense mutations occur in the four predicted transmembrane domains.

Heterozygous *Pmp22* knockout mice display clinical manifestations comparable to HNPP (51). Transgenic mice and rats that overexpress *PMP22* mimic the human disorder (52,53). The finding that such mice also develop a pronounced distal axonopathy (54) led to a reappraisal of disease manifestation in CMT1A, and a careful examination of a cohort of such cases revealed that reduced compound motor and sensory nerve action potentials correlate with clinical disability, while motor NCV does not (55). Consistent with this finding is an earlier observation (56) that motor NCVs and clinical motor examination did not change significantly over a period of 22 years in eight CMT1A duplication cases.

*PMP22* is expressed predominantly in the PNS (42,57). Most of the newly synthesized *PMP22* is retained in the endoplasmic reticulum (ER), where it is degraded (54). Only a small percentage of *PMP22* is transported from the ER to the Golgi, where it undergoes complex glycosylation and becomes more stable. Axonal contact appears to stimulate the redistribution of *PMP22* to the Schwann cell plasma membrane as myelination occurs (58). The ultrastructural pathology of the HNPP phenotype, tomacula formation and reduced myelin compaction (59), suggests that *PMP22* plays a structural role in myelin formation or maintenance, or both.

Strategies aimed at normalizing *Pmp22* expression in transgenic mice have been encouraging (60). When overexpression of *Pmp22* is switched off in adult mice, correction begins within 1 week, and myelination is well advanced by 3 months (although the myelin sheaths are still thinner than normal), indicating that the Schwann cells are poised to start myelination. It has been suggested

that ascorbic acid ameliorates neuropathy in transgenic mice overexpressing *Pmp22* (61); however, extensive studies with human subjects with CMT1A disease did not confirm benefits of the ascorbic acid supplementation (62). The observations of steroid hormone effects on *Pmp22* expression in *in vitro* cultures (63) prompted studies where the effect of progesterone and its antagonist, onapristone, was investigated in a rat model overexpressing *Pmp22*. Interestingly, supplementation with progesterone resulted in increased expression of *Pmp22* mRNA, decreased number of axons on histopathological examination of sciatic nerve, and worsening of the neurological phenotype; conversely, animals supplemented with progesterone antagonist demonstrated opposite findings (64).

**126.6.1.2 Myelin Protein Zero.** The gene for myelin protein zero (MPZ), also known as  $P_0$ , maps to 1q22. MPZ protein contains a single membrane-spanning region, a large hydrophobic glycosylated immunoglobulin-like extracellular domain, and a smaller basic intracellular domain (65). MPZ is normally expressed exclusively by myelinating Schwann cells and accounts for 50% of the total PNS myelin protein (66). More than 120 different myelinopathy-associated MPZ mutations have been described (<http://molgen-www.uia.ac.be/CMTMutations/>). These are mostly associated with CMT1 and sometimes DSN and CMT2 phenotypes. A few cases of CHN have also been reported to be associated with MPZ mutations (67–69). Some evidence suggest that a milder course of CMT disease is associated with heterozygous loss of function MPZ alleles, while severe phenotypes are caused by gain-of-function mutations (70). *In vitro* functional studies were able to demonstrate that the MPZ-truncating mutations associated with a more severe form of peripheral neuropathy result in premature stop codons within the terminal or penultimate exons, and thus, they escape nonsense-mediated decay and are stably translated into mutant proteins (71). A subset of these mutations, despite escaping nonsense-mediated decay, results in a mild form of peripheral neuropathy. Further *in vitro* experiments have demonstrated that the severity of disease phenotype is a result of the retained function of the escaped mutant protein. If the mutant protein has altered function of the cytoplasmic domain and thus impairs adhesion, the mutation acts as a null allele. If the mutation disrupts function of the transmembrane domain, the mutant protein suffers ER retention and protein aggregation, and induces apoptosis (72).

Interestingly, one severe MPZ mutant allele (68) was identified in a patient who presented as a floppy infant and was originally diagnosed with a myopathy, suggesting that innervation may be necessary for proper muscle differentiation and development. The original Roussy-Levy family reported in 1926 has been shown to harbor a point mutation causing a missense amino acid substitution in the extracellular domain of MPZ (30). Thus, mutations in MPZ show a clinically diverse spectrum of CMT and related phenotypes. A recent observation elegantly

demonstrated how various truncating mutations in MPZ convey distinct neurologic phenotypes, depending on whether the truncated mRNA undergoes or escapes nonsense-mediated decay (71). It has been shown that some of MPZ-truncating proteins escape NMD, accumulate at the ER, and trigger apoptosis. Interestingly, supplementation with curcumin, a chemical compound present in the popular turmeric spice, may abrogate ER retention and aggregation-induced apoptosis (72).

Patient genotype–phenotype studies suggest two major types of disease associated mutations: one more severe with early onset and the other type with adult onset (73). Knockout mice heterozygous for *Mpz* mimic the human CMT1 phenotype caused by MPZ mutations (74). Homozygous *Mpz* knockout mice show severe hypomyelination with signs of noncompact myelin (75) and pronounced loss of distal axons (76). The cellular and molecular mechanism of MPZ mutations were studied extensively by Grandis et al. who demonstrated that sequence variants associated with late-onset disease were transported to the membrane and conveyed moderate effect on MPZ-mediated intracellular adhesions. Interestingly, MPZ mutations, causing severe CMT phenotypes, demonstrated multiple gain-of-function effects that resulted in reduction of cellular viability (73).

## 126.6.2 Gene Associated with Transport through Myelin

**126.6.2.1 Connexin 32.** The connexin 32 (*Cx32*) (Gap junction B1; *GJB1*) gene maps to Xq13.1. It consists of two exons and encodes a gap junction protein containing four transmembrane domains. A connexon (hemichannel) consists of six connexin subunits and two connexons, each from one of the two apposing membranes, which form a functional channel that allows rapid transport of ions and small molecules (77). *Cx32* is expressed in myelinating Schwann cells and is localized to noncompact myelin in the paranode and Schmidt-Lanterman incisures consistent with its role in providing a radial diffusion pathway between the adaxonal and perinuclear cytoplasm of the Schwann cell (78,79).

More than 300 different mutations have been described (<http://molgen-www.uia.ac.be/CMTMutations/>). These mutations occur throughout the entire *Cx32* protein and, unlike the *PMP22* and  $P_0$  mutations, are not concentrated in transmembrane or extracellular domains. Mutations in *Cx32* account for nearly 10% of all CMT cases and are the most frequent cause of CMT after *PMP22* duplication. The nature of the neuropathy in CMTX, whether primarily axonal, demyelinating, or a mixed neuropathy, has been debated (80–83). The recent comprehensive evaluation of 73 male patients with CMT1X and 28 *GJB1* mutations revealed that most mutations render a clinical phenotype similar to that observed in patients with a whole gene deletion. These data suggest that the neuropathy phenotype is caused by loss of function mechanism.

It has been proposed that *GJB1* mutations lead to axonal loss rather than demyelination (84).

Cx32-deficient mice mimic the human CMT1X phenotype (85). These mice develop a slowly progressing demyelinating neuropathy, with enlarged periaxonal collars, abnormal noncompacted myelin domains, and axonal sprouts (86). This suggests that reflexive gap junctions may be required for myelin compaction; or alternatively, Cx32 may play a structural role in myelin compaction. Mice lacking Cx32 show a distinct pattern of gene dysregulation in Schwann cells (87), indicating that Schwann cell homeostasis is critically dependent on the correct expression of Cx32.

### 126.6.3 Genes Associated with Axonal Transport

**126.6.3.1 Neurofilament Light Chain.** Neurofilament light chain (*NEFL*) encodes for one of the three subunits of neurofilaments, which are the major type of intermediate filaments found in neurons. Mutations in *NEFL* have been originally identified in two independent families associated with AD CMT2 (88,89). Recent studies, (90–92), have identified additional mutations in *NEFL* among CMT and DSN cases. In the earlier study (90), individuals harboring *NEFL* mutation had an early onset, severe CMT, or DSN phenotype with moderate to severely reduced NCVs. *In vitro* functional studies with mutated *NEFL* demonstrated defects in the assembly of intermediate filament networks, defective targeting of neurofilaments into processes, and altered intracellular distribution of mitochondria, suggesting defective axonal transport as an underlying pathomechanism (93). Yum et al. reported an autosomal recessive family with four siblings affected with severe, early-onset neuropathy (CMT2E) who were homozygous for p.E210X nonsense mutation. Affected individuals had features of axonal neuropathy as evidenced by neurophysiological tests and histopathological studies of the sural nerves. It has been postulated that p.E210X mutation prevented formation of intraaxonal filament network and exerted its pathogenic effect through a loss of function mechanism (94). *Nefl* knockout mice develop normally and show no overt phenotype (95). In another transgenic model, a point mutation (Leu394Pro) causes massive, selective degeneration of spinal motor neurons accompanied by abnormal accumulations of neurofilaments and severe neurogenic atrophy of skeletal muscles (96). Thus, both mouse mutants are not suitable models for human CMT2.

**126.6.3.2 Kinesin Family Member 1B.** Kinesin family member 1B (*KIF1B*), a member of the kinesin superfamily, encodes a molecular motor that transports specific organelles as cargo along microtubules. It has two isoforms—long (beta) and short (alpha). The alpha form is expressed in a variety of tissues and is responsible for the transport of mitochondria. The beta form is expressed specifically in the neurons. Knockout mice heterozygous for *KIF1B*

have a defect in transporting synaptic vesicle precursors and develop progressive weakness similar to that found in human neuropathies (97). A loss-of-function mutation in the motor domain of human *KIF1B* was identified in a pedigree with AD CMT2. Subsequently, an *MFN2* mutation was segregating with disease phenotype in the same family (98). Thus far, no other mutations of *KIF1B* have been found in human peripheral neuropathy.

### 126.6.4 Transcription Factors Associated with Myelination

**126.6.4.1 Early Growth Response 2.** Early growth response gene (*EGR2*), also known as *KROX20*, maps to 10q21 and consists of two exons that encode for a Cys<sub>2</sub>His<sub>2</sub> type zinc-finger-containing protein. Mouse *Egr2* is implicated in the establishment of myelination, and thereafter, its expression is restricted to myelinating Schwann cells (99,100). Homozygous knockout mice for *Egr2* show disruption in hindbrain segmentation (101,102), and the Schwann cells are blocked at an early stage of differentiation (103). Mutations in human *EGR2* are detected in patients with CMT1, DSN, and CHN and frequently associated with cranial nerve dysfunction and early respiratory compromise (104–107). Most mutations occur in the zinc-finger domain. Functional studies have shown that most *EGR2* mutations affect the DNA binding, and the amount of residual binding directly correlates with transcriptional activity and disease severity (17,107). Recently, it has been demonstrated that DNA binding sites for *Egr2* and *Sox10* are in close proximity, and disease-causing *EGR2* mutations affect *SOX10* binding to regulatory sequences and subsequently disturb myelination (108). Different pathogenic mechanisms are proposed for mutations in the R1 domain of *EGR2*, which is known to bind with NAB corepressors and prevent its interaction with NAB proteins, which leads to an increase in the transcriptional activity of *EGR2* (17). Thus, failure to activate or inactivate downstream genes or deregulation of *EGR2* activity could be a possible pathologic mechanism for the development of the disease phenotype.

**126.6.4.2 SRY-Related HMG-Box Containing Gene 10.** Although mutations in *SOX10* mostly cause a distinct phenotype with peripheral neuropathy, demyelinating leukodystrophy and Waardenburg–Hirschsprung disease (109–111), cases with a pure severe hypomyelinating neuropathy presentation have been reported (109). *In vitro* functional studies of *SOX10* mutations demonstrated clear genotype–phenotype correlations based on whether the mutation results in the escape of nonsense-mediated decay (71). PCWH (Peripheral demyelinating neuropathy, Central dysmyelination, Waardenburg syndrome, Hirschsprung disease, MIM#609136) is a novel clinical phenotype associated with gain-of-function mutations in *SOX10*. The *SOX10* activates Cx32, MPZ, and myelin basic protein (MBP), which play a significant role in Schwann cell differentiation; however, *SOX10* is unable

to regulate the expression of myelin genes independently but rather functions synergistically with EGR2 (108,112).

### 126.6.5 Genes Associated with Signaling

**126.6.5.1 Periaxin.** Human periaxin (*PRX*) maps to 19q13. It encodes a protein consisting of an N-terminal PDZ domain, followed by a basic domain, a nuclear localization signal domain, 57 imperfect tandem pentameric repeats that may have a tripeptide spacer and an acidic domain. Mutations in *PRX* are associated with AR DSN and CMT4F (113–115). *PRX* mutations cause an early-onset, but slowly progressive neuropathy with marked sensory component and often sensory ataxia, moderate to severe reduction of NCVs and demyelination with onion bulb formation (116,117). Alternative splicing results in two forms—L-*PRX* and S-*PRX* (118). S-*PRX* is restricted to the cytoplasm. L-*PRX* is initially seen in the nuclei of embryonic Schwann cells and subsequently in the plasma membrane of myelinating Schwann cells (119). It is expressed in the first uncompacted lamellae of the Schwann cell membrane that ensheathes the axon, and further synthesis of the protein in the rat sciatic nerve parallels the deposition of myelin (120). In the mature myelin, *PRX* is found in the cytoplasm-filled periaxonal regions of the sheath but is excluded from the compact myelin. Mice disrupted for *Prx* develop PNS compact myelin that degenerates as the animals age (121) consistent with the requirement of *PRX* in myelin stability. These mice are an important model for the study of neuropathic pain in late-onset demyelinating disease. To date, more than 10 mutations to *PRX* were reported. Interestingly, all mutations are loss of functions (nonsense and frameshift) and are predicted to result in truncated proteins (<http://molgen-www.uia.ac.be/CMTMutations/>).

**126.6.5.2 Myotubularin-Related Protein 2.** Myotubularin-related protein 2 (*MTMR2*) maps to 11q22 and encodes for a dual-specificity phosphatase. It also contains a GRAM domain, a SET-interacting domain, and a PDZ-binding domain. Mutations in *MTMR2* cause a type of AR CMT1 (CMT4B1) and CHN (122,123). CMT4B1 is characterized by focally folded myelin. The mutations are distributed throughout the open reading frame. *MTMR2* uses the lipid second messenger, phosphoinositol 3-phosphate, (PI[3]P), as a physiologic substrate. The known (124) disease-associated *MTMR2* mutations show reduced phosphatase activity (125), indicating that the phosphatase activity of *MTMR2* is crucial for its proper function in the PNS. A mouse model of CMT4B1 neuropathy demonstrates phenotypic findings observed in human subjects with *MTMR2* mutations, including myelin infoldings and outfoldings present in peripheral nerves (126).

**126.6.5.3 SET Binding Factor 2.** SET binding factor 2 (*SBF2*) maps to 11p15 and encodes for an *MTMR2*-related protein. *SBF2* is a member of the pseudophosphatase branch of myotubularins (it is also known as *MTMR13*). A homozygous inframe deletion encompassing exons 11

and 12 was detected in a consanguineous Turkish family (127). Recently, the Japanese family from one of the clinical reports of CMT and glaucoma (128) was found to have a nonsense mutation in *SBF2* that segregated with a phenotype of markedly decreased NCV, myelin folding, and juvenile-onset glaucoma (129). It is expressed in various tissues including spinal cord and peripheral nerve. The histopathologic hallmarks of the disease phenotype are focal outfoldings of myelin in nerve biopsies.

**126.6.5.4 N-Myc Downstream-Regulated Gene 1.** N-myc downstream-regulated gene (*NDRG1*) maps to 8q24 and encodes for a phosphatase. A homozygous C-to-T transition in exon 7 (R148X) was identified in 60 individuals affected with hereditary motor and sensory neuropathy, Lom type (HMSNL) (130). HMSNL is an AR CMT1 type of disorder with deafness and unusual neuropathologic features (131). *NDRG1* is ubiquitously expressed and appears to play a role in cell growth and differentiation.

### 126.6.6 Genes Associated with Endocytic Recycling

**126.6.6.1 RAB7.** Ras-related protein 7 (*RAB7*) encodes a GTP-binding protein that is a member of the RAB family of small GTPases, which are important regulators of vesicular transport and are located in specific intracellular compartments. *RAB7* is universally expressed and has been localized to the cytosolic side of some intracellular organelles. The protein has been shown to be important in membrane trafficking including the late endocytic pathway and retrograde axonal transport (132–134). Mutations in *RAB7* have been associated with CMT2B, an axonopathy (135). The disease-causing mutations in *RAB7* target highly conserved amino acid residues and result in an abnormal GTP hydrolysis rate that may influence axonal transport (134).

**126.6.6.2 SH3TC2.** Mutations in *SH3TC2* result in early onset, slowly progressive neuropathy with frequent spine and foot deformities, and they are identified in 10 to 26% of patients with a CMT4 phenotype making this gene a significant contributor to autosomal recessive CMT or CMT4 (127,136). The gene encodes a 144-D protein that is exclusively expressed in Schwann cells and involved in endocytic membrane trafficking. The protein is localized to the plasma membrane and perinuclear recycling compartment. *In vitro* studies demonstrated that *SH3TC2* interacts with Rab11, a small GTP-ase that regulates the recycling of membranes and receptors to the cell surface. Interestingly mutations identified in CMT4C patients abate protein–protein interactions between *SH3TC2* and *RAB7* that disturbs the endocytic and membrane recycling pathway (137,138).

Recently, the whole genome-sequencing approach was utilized to identify sequence variants in a proband with a CMT type I phenotype and resulted in the identification of two disease-causing mutations in the *SH3TC2*. This was one of the first studies documenting a successful

application of this powerful technique for identification of causative mutations. Interestingly, extended clinical and molecular analysis of the index family revealed that *SH3TC2* haploinsufficiency confers predisposition to a mild polyneuropathy with particular susceptibility to the carpal tunnel syndrome (139).

**126.6.6.3 FIG4.** FIG4 exhibits lipid phosphatase activity toward phosphoinositides and metabolizes phosphoinositol 3,5-bisphosphate, PI(3, 5)P<sub>2</sub>, which plays a role in intracellular signal transduction. The studies of fibroblasts obtained from FIG4-deficient patients demonstrated decreased cellular concentrations of PI(3, 4)P<sub>2</sub> and abnormal intracellular transport of organelles (140). The importance of phosphoinositides (PI) in the regulation of intracellular membrane trafficking has been known for years, and abnormal PI metabolism has been associated with other AR forms of CMT including those caused by mutations to *MTMR2* and *MTMR13* (123,141). Patients deficient for FIG4 present with atypical peripheral neuropathy with severe motor dysfunction and rapid progression. There is an animal model deficient for FIG4 activity, *plt*, pale tremor mouse, that presents symptoms of severe tremor and abnormal gait.

**126.6.6.3.1 LITAF (SIMPLE).** *LITAF* (lipopolysaccharide-induced tumor necrosis factor- $\alpha$  factor), also known as *SIMPLE* (small integral membrane protein of the lysosome/late endosome) and *PIG-7* (p53 inducible gene-7), encodes for an unglycosylated small integral membrane protein that localizes to lysosomes/late endosomes (142,143). The function of the protein remains unknown; however, it has been proposed to play a role in protein degradation. Bioinformatics analysis suggests that *LITAF* may be a member of RING-finger motif-containing subfamily of E3 ubiquitin ligases (144). Mutations in *LITAF* may cause both demyelinating and axonal neuropathy, and they are found in <1% of cases with CMT1 (145–147).

## 126.6.7 Mitochondrial Function Genes

**126.6.7.1 GDAP1.** Ganglioside-induced differentiation-associated protein (*GDAP1*) encodes a ganglioside-induced differentiation-associated protein originally isolated using a tetracycline-regulated expression system from differentiated Neuro2a cells (148). It is expressed at high levels in the brain and spinal cord, and at lower levels in human sural and mouse sciatic nerves (149). The *GDAP1* mutations affect both Schwann cells and neurons and elicit distinct phenotypes including (i) AR demyelinating CMT4A, (ii) AD axonal CMT2E, (iii) AR CMT2 with vocal cord paresis and hoarseness, and (iv) AR intermediate CMT (149–153). Mutations are among the most frequent cause of AR CMT and present in up to 25% of patients (154). The gene encodes a mitochondrial fission factor that plays an important role in mitochondrial division.

The functional studies of disease-causing sequence variants demonstrated that autosomal recessive phenotypes are caused by decreased fission capacity of mutant protein. Dominant mutations to *GDAP1* result in

mitochondrial damage that lead to increased production of reactive oxygen species and increased susceptibility to apoptotic stimuli (155–157).

**126.6.7.2 Mitofusin 2.** Mutations in mitofusin 2 (*MFN2*) are the most frequent cause of the axonal form of CMT neuropathy (98,158–160). Most patients have a moderately severe axonal neuropathy, with onset in childhood. *MFN2* is localized to the outer mitochondrial membrane, and it regulates mitochondrial network architecture by fusion of mitochondria. Mitochondria are dynamic organelles and highly motile with frequent fusion and fission. The potential role of *MFN2* in axonal transport was suggested upon demonstration of its interactions with the *Miro/Milton* complex that connects mitochondria to kinesin motors and plays a crucial role in mitochondrial motility and fusion–fission dynamics (155,161). Although *MFN2* is ubiquitously expressed in the peripheral nerve, the mitochondrial network has to be maintained for long distances from the cell body. This may explain the length-dependent axonal neuropathy developing in patients with *MFN2* mutations (160). Patients with *MFN2* mutations present with normal or slightly decreased NCVs and evidence of axonal degeneration with accumulation of abnormal mitochondria in the axonal periphery (155,162). The mouse model expressing p.T105M mutation replicates the clinical features of CMT2A neuropathy and shows typical histopathological findings observed in patients with *MFN2* mutations (163).

## 126.6.8 Chaperones

**126.6.8.1 Heat-Shock Protein 27 and Heat-Shock Protein 22.** Small heat-shock protein 27 (*HSP27*) mutations were found in distal motor neuropathy and in a family with CMT (164). In this case, distal motor neuropathy and CMT are allelic, suggesting that these two groups of disorders are intimately related. Although *HSP22* mutations were originally found in the distal motor neuropathy group (164), as anticipated, recently an *HSP22* mutation was identified in a family with CMT (165). The pathomechanism of the development of neuropathy is less clear. In vitro data suggest that neuronal cells transfected with mutant *HSP27* are less viable than cells transfected with the wild-type protein. When the mutant *HSP27* is cotransfected with NEFL, neurofilament assembly is altered. In a yeast two-hybrid system, *HSP22* and *HSP27* were found to interact (166).

## 126.6.9 Genes Associated With DNA Single-Strand Break Repair

**126.6.9.1 Tyrosyl DNA Phosphodiesterase 1.** Tyrosyl DNA phosphodiesterase 1 (*TDPI*) maps to 14q32 and codes for a DNA repair enzyme that repairs abortive single-strand breaks (SSBs) created by topo1 (167) and also repairs 3'-phosphoglycolated overhangs of DNA double-strand breaks (DSBs) (168). In the repair of SSBs,

TDP1 cleaves the covalent bond formed between the tyrosine moiety of TopoI and the 3' end of the DNA and thus generates a 3' end compatible with ligation (169). In the case of DSBs that leave a 3'-phosphoglycolate overhang, TDP1 removes the glycolate to leave a 3' phosphate, which forms the substrate for ligation. One familial homozygous *TDP1* mutation has been associated with AR spinocerebellar ataxia and axonal neuropathy (SCAN1) (170). *In vitro* functional studies revealed that mutations associated with the SCAN1 phenotype alter the sequestration of TDP1 into multiprotein single-strand break repair complexes, making these complexes catalytically inactive (171). Another set of *in vitro* functional studies showed that these mutations abolish the 3'-phosphoglycolate processing activity of the enzyme (172). The phenotype caused by mutations in *TDP1* does not quite classify as CMT, because central nervous system involvement is also present. Rather, it belongs to a new group of disorders affecting oculomotor praxis, the cerebellum, the spinal cord, and the peripheral nerves in various combinations. These disorders are caused by alteration of the DNA repair pathways and include the ataxia-oculomotor apraxias type 1 and 2 (AOA1 and AOA2) (173,174). AOA1 results from mutations in aprataxin (175), a protein shown to act in the single-strand DNA break/repair (SSBR) complex (176). AOA2 is due to mutations in senataxin (174), and other mutations of this protein have been associated with familial ALS (177).

### 126.6.10 Genes Associated with Other Peripheral Nervous System-Specific Functions

**126.6.10.1 Lamin A/C.** Lamin A/C (*LMNA*) maps to 1q21 and encodes a structural protein with similarity to cytoplasmic intermediate filament proteins. One familial mutation in *LMNA* is associated with AR CMT2 (CMT2B1) (178). Other mutations in *LMNA* are associated with several different disorders including Emery-Dreifuss muscular dystrophy (EDMD) (179), limb-girdle muscular dystrophy (180), dilated cardiomyopathy (181), familial partial lipodystrophy (182), and mandibuloacral dysplasia (183). Thus, mutations in a single gene can cause different diseases affecting diverse tissues and organs including neurons, muscles, cardiovascular and skeletal systems, and fat cells.

Lamins are the major structural proteins of the nuclear lamina underlying the nuclear membrane. They appear to play a role in DNA replication, chromatin organization, spatial arrangements of nuclear pore complexes, nuclear growth, and anchorage of nuclear envelope proteins (184). Mice, lacking *Lmna*, develop to term with no overt abnormalities (185). However, their postnatal growth is severely retarded and is characterized by the appearance of muscle weakness.

### 126.6.10.2 Potassium Chloride Cotransporter 3.

Potassium chloride cotransporter 3 (*KCC3*) maps to 15q13 and codes for a  $K^+$ - $Cl^-$  cotransporter. Mutations in *KCC3* are associated with AR peripheral neuropathy with agenesis of the corpus callosum (MIM 604878; 218000), also known as Andermann syndrome (186). Heterozygous mice transgenic for deletion of the mouse homolog *Slc12a6* are indistinguishable from the wild type in appearance and gross behavior; however, homozygous animals exhibited weakness of the rear limbs beginning at 2 weeks. Hypomyelination, myelin decompaction, demyelination, axonal swelling, and fiber degeneration were observed in the sciatic nerves of homozygous mice. *KCC3* protein is detected in the brain and the spinal cord and, at low levels, in the dorsal root ganglion (42,186).

**126.6.10.3 Protein Synthesis.** Mutations in four genes encoding aminoacyl-tRNA synthetases including glycyl- (*GARS*), tyrosyl- (*YARS*), alanyl- (*AARS*) and lysyl- (*KARS*) synthetases have been identified in patients with CMT type 2 axonal neuropathies. The genes encode aminoacyl tRNA synthetases involved in charging tRNAs with their cognate amino acids. For the vast majority of ARS, there are separate genes encoding cytosolic and mitochondrial enzymes. The mechanism leading to the pathology remains an enigma. It has been hypothesized that mutations in ARS. (i) change the structure of ARS and allow misincorporation of amino acids; (ii) decrease enzymatic activity that in turn affects protein synthesis; and (iii) result in mislocalization in cellular compartment (187–189). Mutations in glycyl tRNA synthetase (*GARS*) have been found in patients with AR CMT axonal neuropathy type 2, designated CMT2D (190). Distal spinal muscular atrophy type V (DSMAV) is an allelic disorder with a similar phenotype. The clinical picture of patients with *GARS* mutations was different from other axonal CMT2 types in that weakness and atrophy were more severe in the hands than in the feet, and that sensory impairment had the same prevalence as the motor involvement (191). Patients with mutations in *YARS* present with dominant intermediate neuropathy characterized by intermediate NCVs and histological evidence of both axonal and demyelinating features. The original patients described suffered from the distal leg and arm weakness, numbness, and prominent sensory defects (192). It has been hypothesized that disease-causing mutations may cause a dominant-negative effect on *YARS* in neuronal endings that leads to axonal loss and signs of peripheral neuropathy (193). Alanyl-tRNA synthetase mutations were originally described in two French pedigrees. Affected individuals presented with predominant axonal neuropathy leading to sensory-motor distal degeneration and demyelinations. Both families were found to have the p.Arg329His mutation that was shown to reduce tRNA-Ala aminoacylation in *E. coli* (194). Lysyl-tRNA synthetase mutations were reported in two families with CMT neuropathy. The phenotype of an affected patient with two disease-causing

*KARS* mutations presented with an intermediate form of autosomal recessive CMT disease accompanied by developmental delay and dysmorphic features. Both mutations represent loss of function alleles with severely depressed aminoacylation potential (195).

**126.6.10.4 Dynamin 2.** Mutations in dynamin (*DNM2*) on chromosome 19p12-13.2 were found in three unrelated families with CMT originating from Australia, Belgium, and North America. *DNM2* belongs to the family of large GTPases and is part of the cellular fusion–fission apparatus. *In vitro* experiments showed that mutations of *DNM2* substantially diminished binding of *DNM2* to membranes by altering the conformation of the beta3/beta4 loop of the pleckstrin homology domain. Additionally, two different mutations affecting the same amino acid, Lys558, segregated with CMT and neutropenia, which has not previously been associated with CMT neuropathies (196).

**126.6.10.5 Inverted Formin 2 (IFN2).** Mutations in the inverted formin 2 (*IFN2*) gene were recently identified in patients with CMT neuropathy associated with focal segmental glomerulosclerosis (FSGS). Patients with *IFN2* mutations present with early onset of renal diseases followed by end-stage renal disease (median age 18 years and 21 years, respectively). Their neurological problems including walking difficulties, muscle wasting, and areflexia are frequently seen as early as in the teenage years. These symptoms are accompanied by other CNS abnormalities, for example sensorineural hearing loss and white matter hyperintensities on brain MRI. *IFN2*-associated disease was classified as intermediate AD CMT based on moderate reduction of NCV and the combination of axonal and demyelinating features on nerve biopsy studies. The gene is expressed in both Schwann cells and podocytes. It encodes a formin protein that is involved in intracellular polymerization and depolymerization of actin and other elements of the cytoskeleton. It has been postulated that *IFN2* mutations disturb cytoskeletal networks and targeting of protein to plasma membrane in various types of cells. Interestingly, mutations associated with CMT + FSGS phenotype are localized exclusively in diaphanous inhibitory domain (DID) as opposed to more scattered distribution observed in patients with renal disease alone (197).

## 126.7 CHARCOT–MARIE–TOOTH “DISEASE GENES” REVEAL A CELLULAR AND MYELIN DEVELOPMENT/ MAINTENANCE NETWORK

Genes implicated in the pathogenesis of peripheral neuropathies encode proteins that form a multitiered network of structural proteins, enzymes, and transcription factors that are implicated in development and maintenance of the nervous system. This hierarchy is exemplified by the central position of *SOX10*, which orchestrates spatial and temporal expression of

downstream transcription factors (e.g. *EGR2*) that in turn control expression of myelin genes (*PMP22*, *MPZ*, and others) (Figure 126-4). Further elucidation of these relationships is crucial for better understanding of mechanisms leading to the disease (198).

### 126.7.1 Genetic Testing—Single Locus/Gene Approach

Recent advances in identifying specific mutations in various genes have led to extensive genotype–phenotype correlation studies, which have confirmed and elucidated further that genetic heterogeneity, age-dependent penetrance, and variable expressivity are key characteristics of the HMSN. Molecular tools have increased the possibility of establishing a specific molecular diagnosis. The expense associated with evaluating multiple genes for disease-causing mutations has also escalated. When deciding on genetic testing, one should consider multiple factors, including (i) availability of clinical testing, (ii) the yield of a specific molecular test, (iii) the aim of establishing a molecular diagnosis, and (iv) in sporadic cases, the frequency of *de novo* mutations.

Hereditary polyneuropathy is common, and powerful diagnostic tests are clinically available. Forty loci and 34 genes (see Figure 126-1 and Table 126-1) have been identified in CMT and related peripheral neuropathies, generating a complicated molecular classification and making it difficult to apply the vast amount of information in clinical practice. In order to establish evidence-based guidelines, we recently reviewed the medical literature and identified 10 population-based studies from various ethnic backgrounds (44,45,48,199–206). These studies reported results on five genes or genomic rearrangements: *PMP22* duplication/deletion; *MPZ*, *Cx32*, and *PMP22* point mutations. The mutation frequencies of the individual genes in the total population and in phenotypic subgroups are depicted in Table 126-2. Similar mutation frequencies were detected in the various studies, revealing a uniform distribution of pathogenic mutations. Applying a simple clinical classification (demyelinating versus axonal neuropathy) and considering the inheritance pattern (205) markedly improved the diagnostic yield.

In order to estimate the relative frequencies of the genes for which population-based studies are not available, we used our own cohort of 153 consecutive unrelated CMT cases collected before the availability of genetic testing in commercial laboratories (precommercial era). We have screened 14 genes and genomic rearrangements (*PMP22* dup/del, point mutations in *Cx32*, *MPZ*, *PMP22*, *EGR2*, *PRX*, *NEFL*, *SOX10*, *SIMPLE*, *GDAP1*, *LMNA*, *TDP1*, *MTMR2*) in this cohort to estimate the relative frequency of pathogenic mutations in these genes. The frequencies of the five mutations screened in the population-based studies were similar, suggesting that estimates from this cohort are adequate. Seemingly, mutations in the genes for which population studies are not available

may contribute to only a small minority (<1 to 2%) of patients with the CMT phenotype. Molecular testing in commercial laboratories confirmed the relative frequencies of the various genes harboring pathogenic mutations.

Duplication of a chromosomal segment harboring *PMP22* (i.e. the CMT1A duplication) (2) represents 43% of the total CMT cases, whereas the yield of duplication detection rises to 70% in CMT1. This group of patients represents the potential beneficiaries of the novel therapeutic interventions, and being the most common mutation, it is likely that drug toxicity studies will address this population initially, just like the data of idiosyncratic vincristine toxicity have emerged from patients with this mutation (207,208). Thus, the aim is to identify all subjects with the CMT1A duplication; therefore, the test should be used as a screening test.

The deletion of the same chromosomal segment results in HNPP (40). HNPP can mimic multifocal neuropathy (47), a frequently inflammatory disorder that requires immunosuppressant therapy. The individuals with HNPP among this group of patients need to be identified in order to do no harm. Although detection of deletion has a low yield in the CMT population, the clinical picture is distinctive, and the deletion is specific for HNPP. Thus, testing of this phenotype identifies deletion mutations in >90% of patients. Deletion testing should serve as a confirmatory test. Importantly, essentially all commercially available DNA diagnostic tests for the common CMT1A duplication and HNPP deletion rearrangements can detect either mutation using a single assay.

After the CMT1A duplication and HNPP deletion, *Cx32* mutations are the next most common culprits in inherited neuropathy. A dominant inheritance pattern and lack of male-to-male transmission point to this gene on the X chromosome. Identification of a *Cx32* mutation determines an XL-dominant inheritance pattern, enabling both genetic counseling and accurate estimation of recurrence risk. As the phenotype is intermediate, molecular testing for *Cx32* is appropriate in both CMT1 (after duplication testing) and in CMT2.

The population-based studies suggest that in patients with the CMT1 phenotype *MPZ* and *PMP22* mutations are the next most common after *PMP22* duplication and *Cx32* mutations. In the CMT2 group, recent data, although not population based, suggest that *MFN2* mutations are one of the most common causes of CMT2 present in up to 20% of patients, followed by *Cx32* and *MPZ* mutations in frequency (98,160). *GDAP1* and *SH3TC2* compound heterozygous and homozygous mutations account for a significant fraction of autosomal recessive CMT4.

Mutations in other genes are responsible for the CMT phenotype in only a small minority of patients; however, unique clinical features may point to a specific gene (e.g. *EGR2* external ophthalmoplegia, respiratory compromise; *SBF2* glaucoma or *IFN2* glomerulonephritis)

(Table 126-3). In the absence of a clinical clue, the likelihood of establishing a molecular diagnosis is low.

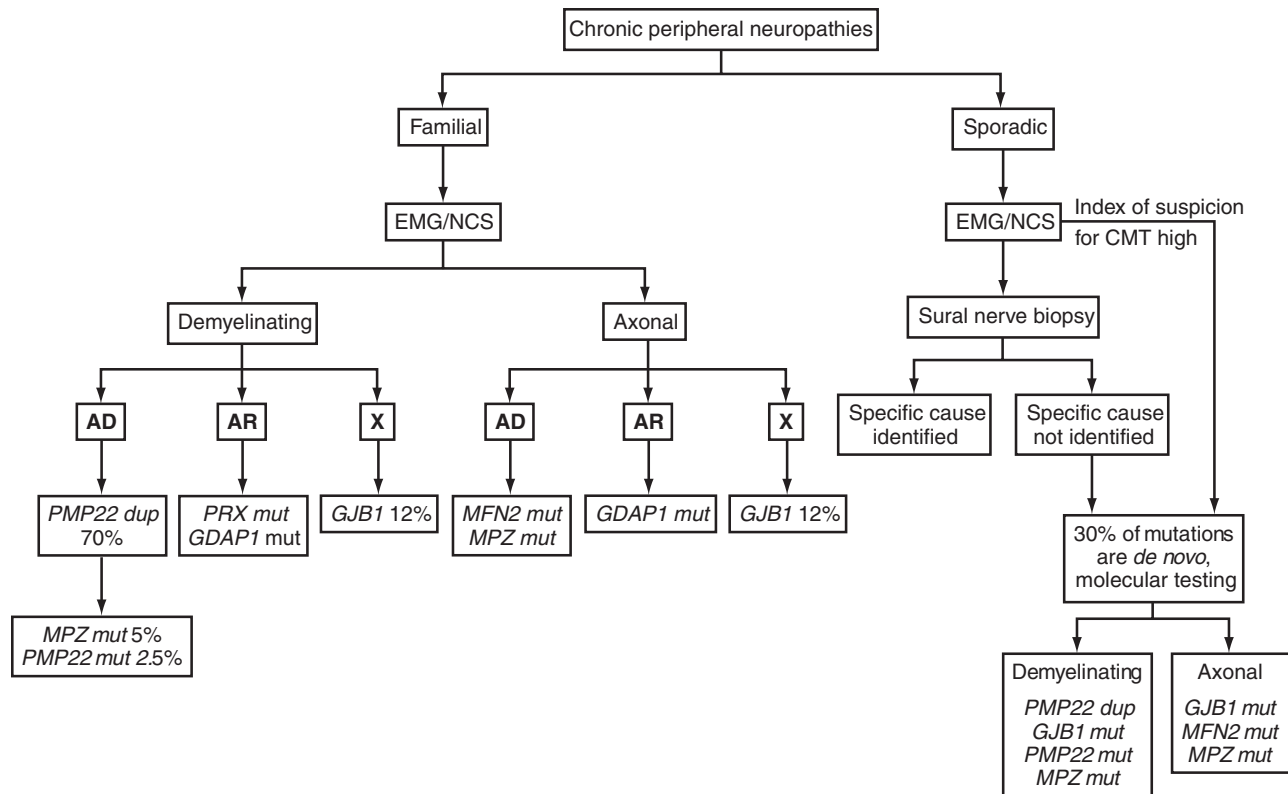

The high frequency of *de novo* mutations in duplication/deletion (37 to 90%) (44,46) illustrates that genetic disease is commonly sporadic in presentation, lacking a family history. Our data suggest that point mutations also occur frequently *de novo* (199). The frequently occurring *de novo* event necessitates having an index of suspicion for genetic disease, even in the absence of a family history. In fact, in a patient presenting with chronic polyneuropathy in the absence of other signs and symptoms, after the most common systemic and treatable causes such as diabetes, uremia, and nutritional deficiency, genetic causes are more common than autoimmune or paraneoplastic neuropathy. A rational diagnostic approach is presented as Figure 126-3.

Finally, when performing genetic testing, one must consider the specific question posed and the likelihood that the result alters medical management. In adults with the CMT phenotype, *PMP22* duplication and *Cx32* mutation analysis establish the molecular diagnosis in 65% of patients. The combination of *PMP22* duplication and *Cx32* mutation testing identifies the candidates for the clinical trials, and in the near future, those who may benefit from treatment with gene expression modifiers (selective progesterone antagonist (64), vitamin C (61)), identifies families whose members are at risk for idiosyncratic drug reactions, and determines the inheritance pattern, establishing grounds for accurate genetic counseling, and prenatal diagnosis. If patients with the demyelinating form are tested as a group, the diagnostic yield increases to over 80% by performing *PMP22* duplication and *Cx32* mutation testing.

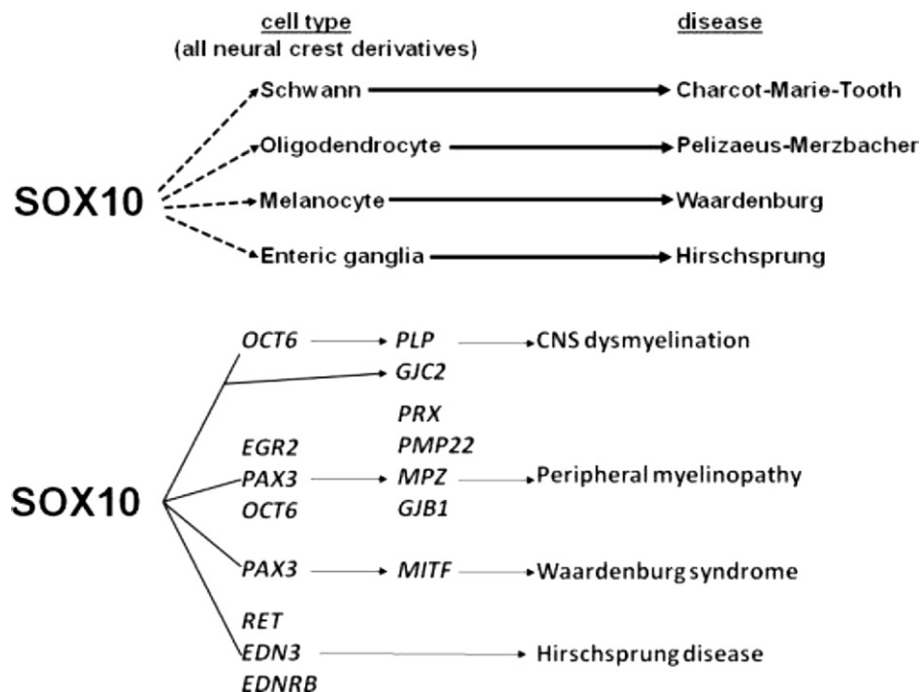

In the pediatric population, the aim of testing has a different emphasis. The parents frequently have a devastated child with severe weakness and normal intellect. The parent's major concerns are prognosis and recurrence risk. The answer will depend on an accurate molecular diagnosis. In children after testing for the common causes of peripheral neuropathy, *PMP22* duplication, and *Cx32* mutations, the physician should consider proceeding to panel testing for all the genes implicated in that phenotype or potentially consider a genome analysis.

### 126.7.2 Genetic Testing—Genome Analysis by Whole Genome/Exome Sequencing

We are now witnessing rapid developments in the field of genomic DNA analysis that is changing the landscape of clinical molecular genetic testing. The introduction of genomic methodology, based on array comparative genomic hybridization (aCGH), single-nucleotide polymorphism microarrays (SNP arrays), and next-generation whole genome or exome sequencing, has already proven its diagnostic and sometimes therapeutic potential (139,209). The application of aCGH and SNP arrays allows detection of disease-causing copy-number changes

**FIGURE 126-3** Flow diagram depicting a stepwise approach in the diagnosis of CMT and related peripheral neuropathies. In cases with a positive family history, electrophysiology establishes the objective diagnosis of demyelinating versus axonal disease. Taking into account the inheritance pattern helps limit the possible causative genes, then testing can proceed in the order from most common to least common. In sporadic cases of peripheral neuropathy, after exclusion of the most common causes of peripheral neuropathy, a sural nerve biopsy may indicate a specific nongenetic etiology or suggest genetic disorder. If the index of suspicion for CMT is high, genetic testing can follow the establishment of the demyelinating versus axonal phenotype by electrophysiology even preceding sural nerve biopsy.

**TABLE 126-2 Mutation Frequencies (%) for CMT and Related Neuropathies in 10 Population Studies**

Phenotype	CMT1A Duplication	HNPP Deletion	PMP22 Mutation	Cx32 Mutation	MPZ Mutation
Total	25–59	11–26	1–4	5–8	1–6
CMT1	54–81	ND	0–2	5–19	2–7
HNPP	ND	84–100	0–20	ND	ND
CMT2	ND	ND	ND	3–57	ND
CMT	3	ND	ND	18	2–40
DSN	ND	ND	14–50	ND	14–25

CMT, Charcot–Marie–Tooth disease; CMT1, Charcot–Marie–Tooth disease type 1; CMT2, Charcot–Marie–Tooth disease type 2; DSN, Dejerine–Sottas neuropathy; HNPP, hereditary neuropathy with liability to pressure palsies.

**TABLE 126-3 Clinical Pearls in CMT**

Gene	Special Features
<b>I. Peripheral neuropathy</b>	
<i>GJB1</i>	1. Early upper extremity involvement
<i>MPZ, NDRG1, PRX</i>	2. Marked sensory involvement
<i>LMNA</i>	3. Proximal weakness
<i>GJB1, MPZ, PMP22</i>	4. Intermittent symptoms
<b>II. Cranial nerve involvement</b>	
<i>PMP22, GJB1, NDRG1,</i>	1. Deafness <i>EGR2, PRX, SOX10</i>
	2. Pupillary abnormalities: MPZ a. Adie's pupil b. Argyl–Robertson pupil
<i>EGR2</i>	3. Ophthalmoplegia
<i>EGR2, MTMR2, PMP22</i>	4. Facial weakness
<i>GDAP1, MTMR2</i>	5. Vocal cord paralysis
<i>EGR2, MTMR2, MPZ</i>	6. Bulbar
<b>III. CNS involvement</b>	
<i>GJB1, SOX10</i>	1. Focal demyelination
<i>PMP22 dup</i>	2. Static tremor
<b>IV. Other organ system</b>	
	1. GI:
<i>MPZ</i>	a. Diarrhea, vomiting
<i>SOX10</i>	b. Pseudoobstruction
<i>NEFL</i>	2. Hyperkeratosis
<i>EGR2</i>	3. Respiratory compromise
<i>MTMR13/SBF1</i>	4. Juvenile glaucoma
<i>DNM2</i>	5. Neutropenia
<i>IFN2</i>	6. End-stage renal disease.
<b>V. Pathology</b>	
<i>MPZ, PRX, MTMR2</i>	1. Focally folded myelin sheaths
<i>NDRG1</i>	2. Intraaxonal curvilinear profiles
<i>PRX</i>	3. Detachment of terminal paranodal myelin loops from the axon and loss of septate-like junctions and transverse bands
<i>IFN2</i>	4. Focal segmental glomerulosclerosis (FSGS)

in patients with various clinical phenotypes. Identification of recurrent and often *de novo* copy-number variant (CNV), the CMT1A duplication (36,210), initiated the molecular genetic revolution in the study of peripheral neuropathy. CMT1A neuropathy represents a classical and one of the earliest examples of genomic disorders,

resulting from a pathogenic copy-number variation (211). Recent studies reveal rare nonrecurrent CNV of different sizes can cause CMT1A or HNPP (212). Furthermore, comprehensive analysis of *GJB1* in patients with a classical CMT1X phenotype but no detectable single nucleotide variants revealed the presence of disease-causing CNVs, disrupting the whole gene (213). We may anticipate that future studies will bring more examples documenting the role of pathogenic CNVs in the etiology of CMT.

Next generation sequencing has been already introduced to clinical laboratories and becoming a reliable and affordable tool to analyze DNA and genomes. Interestingly, one of the first patients ever diagnosed using whole-genome sequencing had CMT type I due to *SH3TC2* mutations (139). The advantages of the whole-genome approaches are especially apparent for disorders like CMT disease that is extremely heterogeneous at both the clinical and molecular levels. The genome-wide analysis with next generation sequencing allows testing all known CMT genes at once. It is expected that this broad approach may enable identification of genetic factors that are modulating the clinical phenotype (modifier genes) and further explain phenotypic heterogeneity. Whole-genome analysis brings also some ethical challenges that need to be addressed prior to its widespread implementation. These challenges are related to discovery and disclosure of unexpected findings generated by whole-genome studies, including carrier status of AR conditions, mutations in genes predisposing to late-onset diseases, or unexpected familial relations e.g. nonpaternity, incest, or consanguinity. Whole genome sequencing does not detect the CMT1A duplication; testing for CMT1A duplication/HNPP deletion should be performed prior to instituting whole genome sequencing.

### 126.7.3 Management

Treatment approaches to the HSMNs can be divided into preventive, symptomatic, and etiologic approaches. Treatment is directed to maintain function of joints and muscles. Because CMT is a slowly progressive neurodegenerative disease, these areas need to be assessed periodically. Physiotherapy and occupational therapy aid in maintaining range of motion and thus help in functioning (214,215). After a thorough evaluation, the patient and family are

**TABLE 126-4** Partial Listing of Neurotoxins Associated with Peripheral Neuropathy

Drugs	Heavy Metals	Organic Chemicals
Amiodarone	Arsenic	Ethanol
Amphotericin	Lead	Carbon monoxide
2',3'-dideoxycytidine	Mercury	Carbon disulfide
2',3'-dideoxyinosine	Thallium	Cyanate
2',3'-didehydro-3'-deoxythymidine		N-hexane
Cisplatin		Hydroxyquinolines
Ethambutol		Organophosphates
Ethionamide		Triorthocresyl phosphate
Isoniazid		
Lithium		
Metronidazole		
Nitrofurantoin		
Phenytoin		
Taxanes		
Thalidomide		
Vincristine		

instructed on an exercise program that can be carried out at home with periodic reassessments to modify the program, if needed, in the light of changing manifestations of the progressive disorder. The application of orthotic devices and assistive equipment can be made, if warranted. High top shoes, and with progression, ankle-foot orthoses can stabilize weak ankles and improve gait (216). Such intervention rarely requires prolonged care by the physician or occupational therapist. In some instances, surgical interventions for the hands and feet are necessary (217,218).

Symptomatic treatment may have a substantial impact on the patient's quality of life. Maintenance of normal weight prevents strain on weak muscles and joints, and maintains ambulation longer. Excess weight and the development of low back pain correlates with CMT, as well as in other neurologic disorders. Nonsteroidal antiinflammatory drugs may help to relieve lower back or leg pain. In cases in which neuropathic pain develops, antiepileptic drugs (gabapentin, topiramate) or tricyclic antidepressants (amitriptyline) can be used (219–221). The tremor may respond to beta blockers or primidone (222). Caffeine and nicotine can aggravate the fine intentional tremor, therefore avoidance of these substances is recommended. Neurotoxic drugs (Table 126-4) and excessive alcohol should be avoided. A list of such drugs is available with the Charcot–Marie–Tooth Association (<http://www.charcot-marie-tooth.org/>). Vincristine, a cancer chemotherapeutic agent, causes neuropathic side effects in a dose-limiting manner (223). A small dose of vincristine can produce a devastating effect in CMT patients (207). However, early detection of HMSN can avoid life-threatening vincristine neurotoxicity (224).

Although etiologic treatment is currently unavailable, recently, two potential small molecule therapeutic

approaches (61,64) have proved effective in the treatment of animal models for a specific molecular form of CMT neuropathy due to the CMT1A duplication. A selective progesterone antagonist slowed the progression of peripheral neuropathy in a transgenic rat model of CMT1A caused by overexpression of *Pmp22*, whereas vitamin C therapy slowed progression of neuropathy in a mouse model of CMT1A duplication; however clinical trials of vitamin C in patients with CMT1A duplication showed no demonstrable benefit. These observations will initiate clinical trials in patients with the CMT1A duplication and may prove as etiologic therapy for this specific molecular diagnosis.

## 126.8 GENETIC COUNSELING

Because CMT follows the principles of Mendelian inheritance, genetic counseling for recurrence of CMT1 and CMT2 is relatively straightforward if the family history for an affected individual is defined. Because of intrafamilial variability in disease expression, the definition of parental disease status requires either testing for a mutation defined in the proband or, if the mutation is not identifiable, a thorough neurologic examination with objective nerve conduction studies.

### 126.8.1 Positive Family History

An affected parent with AD or XL-dominant CMT1 or CMT2 has a 50% risk of having a child with the same mutation. The risk that a child with a mutation will be clinically affected sometime during his or her life is not known, however, because the clinical penetrance of CMT1 and CMT2 has not been determined for genetically well-defined patient populations. In general, though, few patients with AD CMT1 have substantial difficulty walking before age 50 years, although most, if not all, patients express some symptoms by the sixth decade of life (27). Similarly, only a small percentage of patients with AD CMT2 have substantial difficulty walking before age 50 years, and a small number may remain unaffected throughout life. For fathers with XL-dominant CMT, the risk of having an affected son is negligible, but the risk of having an affected daughter is 50%, whereas, for mothers with XL-dominant CMT, the risk of having an affected son or daughter is 50%.

The risk of developing AD CMT1 can be assessed by DNA testing if the causative mutation is known or by electrophysiology if the mutation cannot be identified. For AD CMT1, NCV slowing is detectable by age 2–5 years (225,226); therefore, if a young adult has normal NCVs, his or her risk of developing AD CMT1 is negligible, whereas if the NCVs are abnormal, the patient has at least a 90-% lifetime risk of developing symptoms.

In contrast to CMT1, DNA testing for CMT2 leads to a molecular diagnosis in a smaller percentage of patients, and the electrophysiologic changes associated with AD CMT2 develop with disease progression. Because of

these confounding factors, only about half of patients can be identified by age 20 years (29).

Most AR forms of CMT manifest in childhood or early adolescence. The risk of a young adult developing AR CMT is, therefore, low.

### 126.8.2 Negative Family History

For unaffected parents with a child affected with CMT1 or CMT2, four possibilities exist: a *de novo* dominant mutation in the affected child, AR inheritance, XL inheritance, or nonpaternity. Distinction between these possibilities requires either the identification of the causative mutations or identification of affected siblings. The identification of a *de novo* heterozygous presumed dominant mutation suggests a low recurrence risk for the parents; however, the risk is higher than that for the general population because of germline mosaicism (227,228). A proband with a heterozygous presumed dominant mutation has a 50-% risk of having affected children. For AR inheritance, the parental risk of an affected child is 25% because penetrance is nearly complete.

## 126.9 SUMMARY

CMT represents a clinically and genetically heterogeneous group of disorders, caused by aberration of the intimate relationship between the Schwann cell sheath and the neural axon. The clinical symptoms of weakness and muscle atrophy, and DSP, ultimately results from axonal death and muscular denervation, the final common pathway of nerve damage. A simple clinical classification of CMT (demyelinating versus axonal) improves the yield of genetic testing and determines which genes should be tested for. In the demyelinating form, the combination of CMT1A duplication and Cx32 mutation testing has a yield of approximately 80%. MPZ and PMP22 mutations are the next most common culprits. In cases of axonal CMT, MFN2 mutations are most prevalent and present in 20% of patients with CMT2 followed by mutations to MPZ and Cx32 in the population-based studies. For AR CMT, GDAP1 and SH3TC2 appear to be significant contributors to disease. Recent discoveries of potential small molecular treatments for a specific subtype of CMT shifted the emphasis in genetic testing: instead of a molecular diagnosis for the few patients referred to tertiary care centers, we need to find most patients with the potentially treatable molecular pathomechanism. Although the robust amount of new information taught us about peripheral nerve function and dysfunction, it also made genetic testing for all known genes impractical in clinical practice. However, the low cost of genome analysis may make this approach very pragmatic after PMP22 duplication/deletion analysis (229). Today, genetic testing should be used to address specific questions in a logical stepwise fashion based on evidence from population-based studies. However, the

introduction of powerful new genomic analysis tools may dramatically change clinical genetic testing and obviate the need for the disease gene panel testing in genetically heterogeneous conditions like CMT.

### Biographies

**Wojciech Wiszniewski** is Assistant Professor at the Department of Molecular and Human Genetics. He received his MD degree from Medical University of Warsaw and PhD from National Research Institute of Mother and Child in Warsaw, Poland. Dr Wiszniewski completed residency training in medical genetics in 2011 at Baylor College of Medicine, Houston, TX. He has studied the mechanisms of Charcot–Marie–Tooth (CMT) neuropathies in Dr Lupski’s laboratory.

**Kinga Szigeti** is Assistant Professor of Neurology. Dr Szigeti received her MD at the University of Pecs, Hungary in 1994. In 1997 she moved to the United States and completed a postdoctoral fellowship at Harvard University. She completed her clinical training in neurology (1998–2002) at the University at Buffalo and medical genetics (2002–2004) at Baylor College of Medicine. She studied Charcot–Marie–Tooth disease in Dr Jim Lupski’s lab. She was instrumental in developing evidence-based guidelines for genetic testing in CMT and related peripheral neuropathies. She is a neurogeneticist and neurologist with special interest in peripheral neuropathies and Alzheimer’s disease. She has coauthored 28 scientific publications and is a coinventor on two patents.

**Jim Lupski** is Cullen Professor and Vice Chair of Molecular and Human Genetics. Dr Lupski received his initial scientific training at the Cold Spring Harbor Laboratory as an Undergraduate Research Participant (URP) and at New York University completing the MD/PhD program in 1985. In 1986 he moved to Houston, Texas for clinical training in pediatrics (1986–1989) and medical genetics (1989–1992) and then established his own laboratory at Baylor College of Medicine where he remains, and as of 1995, as the Cullen Professor of Molecular and Human Genetics. Through studies of Charcot–Marie–Tooth peripheral neuropathy, a common autosomal dominant trait due to a submicroscopic 1.5-Mb duplication, and Smith–Magenis syndrome, a contiguous gene deletion syndrome, his laboratory has delineated the concept of “genomic disorders” and established the critical role of copy-number variation (CNV) and gene dosage in conveying human disease phenotypes. An increasing number of human diseases are recognized to result from recurrent DNA rearrangements (recent examples include obesity and both autism and schizophrenia), involving unstable genomic regions and have thus been classified as genomic disorders. Dr Lupski’s laboratory has also used chromosome engineering to develop mouse models for genomic disorders. Recently, the laboratory’s CMT studies in collaborations with Richard Gibbs and the Baylor Human Genome Sequencing Center resulted in the first personal genome sequence to identify a “disease gene” by whole genome sequencing (WGS) and demonstrated the utility of WGS for optimizing patient management. These latter investigations further elucidated the potential role of rare variants in complex traits such as carpal tunnel syndrome and fibromyalgia. For his work on human genomics and the elucidation of genomic disorders, Dr Lupski was awarded a Doctor of Science degree honoris causa in 2011 from the Watson School of Biological Science at the Cold Spring Harbor Laboratory. He has coauthored over 500 scientific publications, is a coinventor on more than 20 patents, and has delivered over 400 invited lectures in 32 countries.

### 127.1 INTRODUCTION

The term “congenital myopathies” does not, as the name might imply, refer to just any inborn primary myopathy. Rather, it is used to designate a group of congenital muscle disorders defined on the basis of structural abnormalities of the muscle fibers, which are visible after staining of muscle biopsy sections by histochemical methods. This chapter addresses the most clearly defined entities within this group. A report by Goebel and Bönnemann describes some of the more unusual structural myopathies (1). The current use of the term congenital myopathies does not include the muscular dystrophies, metabolic myopathies, or mitochondrial disorders, although in individual cases there may be considerable clinical and histopathological overlap.

Congenital myopathies are rare. The incidence of all congenital myopathies taken together is estimated to be around 0.06 per 1000 live births, or one-fifth of the incidence of Duchenne muscular dystrophy and one-tenth of all cases of neuromuscular disorders (2). The prevalence of all congenital myopathies in the adult and pediatric population in northern Ireland, UK, and in the pediatric population of western Sweden is estimated to be 1:28,600 and 1:22,480, respectively (3,4); however, these data are likely to be an underestimate as patients often present with only subtle clinical and pathological manifestations.

### 127.2 DIAGNOSIS

#### 127.2.1 Clinical Features

The congenital myopathies are characterized by generalized muscle hypotonia and weakness of varying severity. They cannot be distinguished from each other or other congenital muscle disorders on clinical grounds alone; diagnosis is dependent on muscle biopsy findings. These, in turn,

require the use of histochemical staining methods applied to fresh-frozen sections of the sample. There are, however, some differences between the disorders in their predilection for, and distribution of, muscle weakness and in their associated features. These are discussed later separately for each disorder. A systematic diagnostic approach for the congenital myopathies outlined by an international group of experts has been published (5). Many of the causative genes implicated in the congenital myopathies have now been identified, a majority of them encoding sarcomeric proteins and proteins directly involved in calcium homeostasis and excitation–contraction (EC) coupling (Table 127-1).

Many patients present at birth with severe floppiness and muscle weakness, and have difficulties with respiration and feeding. Arthrogryposis is not a characteristic feature, with the exception of rare, very severe cases (44,45). The face is often elongated and expressionless, the mouth tent-shaped, and the palate high-arched (Fig. 127-1). Retrognathia and later jaw lock from masseter contractures may occur. In some patients, chest deformity is evident at birth. These features are likely to be secondary to muscle weakness, as are the commonly encountered foot deformities and hip dislocations. The dysmorphic features do not amount to, but can be reminiscent of, Marfan's syndrome (46–48) or 22q11.2 deletion syndrome. Most other patients present later in infancy or childhood with delayed attainment of motor milestones and a waddling gait, and some with a disturbance of speech articulation.

Clinical presentation later in life is infrequent, but occasionally mild congenital muscle weakness may go unnoticed and patients may thus present in adulthood, either with progressive weakness or with respiratory insufficiency. These patients usually lack the dysmorphic features and deformities that are thought to be secondary to congenital muscle weakness (49). In many adult-onset cases, it remains to be determined how frequently the

AD, autosomal dominant; AR, autosomal recessive; X, X-linked; MmD, multi-minicore disease; MFM, myofibrillar myopathy.

histologic findings suggestive of a congenital myopathy are in fact due to non-hereditary disease processes, such as for example in sporadic late-onset nemaline myopathy (50), see also Section 127.5.

Some infants die from respiratory complications, but even patients with severe floppiness and lack of spontaneous respiration at birth have been known to survive, some of them with little residual disability (51–57). Others may experience deterioration during the prepubertal period of rapid growth, and some will require a wheelchair from this time. Otherwise, the course of the disease is often only very slowly progressive, and most patients will be able to lead an active life.

The main factors influencing prognosis seem to be respiratory capacity and the development of scoliosis (56,58,59). In many congenital myopathies the diaphragm along with the intercostal muscles and the accessory muscles of respiration are affected; this is of special

importance during sleep and when the patient is in the recumbent position. The monitoring of respiratory function and of the spine are essential elements in the ongoing care of these patients (60). Respiratory infections are common in the preschool years, but this susceptibility is often overcome with time (53,61).

The gait is usually waddling because of pelvic girdle weakness, and some patients have foot drop. The build is slender but muscle bulk is not necessarily small, especially not in young children. The spine is hyperlordotic or sometimes rigid (24,56,62–66). Tendon reflexes are weak or absent. Gross motor activity is slow, whereas fine motor activity is normal. Many patients have hypermobility of joints, and contractures and deformities of the joints commonly develop with time.

Intelligence is usually normal. Cardiac involvement is uncommon in association with most of the currently known genetic defects, but an initial evaluation to exclude

**FIGURE 127-1** A 3½-year-old girl with congenital nemaline myopathy. Note myopathic facies, chest deformity, and hyperlordotic posture.

structural cardiac abnormalities or a cardiomyopathy is indicated as in other neuromuscular conditions. Cardiac follow-up is necessary when hypoxia carries the risk of cor pulmonale (58), in genetically unresolved cases and probably also in patients with mutations in the skeletal  $\alpha$ -actin gene, because of the late expression of this gene in cardiac muscle (67) and rare reports of an associated cardiomyopathy (68).

Although a variety of abnormalities interpreted as neurogenic have been reported (69–71), most patients will have normal findings on examination of peripheral nerves, including normal conduction velocities. Autopsy findings in the central nervous system (CNS) and peripheral nerves have also been normal in most cases (72–74). Electromyography (EMG) may be normal in young patients and mild cases but usually shows polyphasic motor unit potentials with small amplitude, a full interference pattern during weak effort, and normal

fiber density (75,76). In addition to these “myopathic” features, EMG signs often interpreted as neurogenic, such as large motor unit potentials with discrete pattern on full effort, abnormal jitter, and increased fiber density, may develop with time, especially in distal muscles (75,77–80). In some patients, neurophysiological assessment may suggest an associated neuromuscular transmission defect (81). Severely affected neonates may even show spontaneous activity to the extent of mimicking spinal muscular atrophy (8,72,76,82–87).

Ultrasonography often shows abnormally high echogenicity in affected muscles and computed tomography (CT) shows low density of muscles with preservation of volume. Magnetic resonance imaging (MRI) commonly reveals fatty infiltration of the muscle tissue (88–91) and often identifies patterns of selective muscle involvement, which may aid the genetic diagnosis in individual cases (see paragraphs on specific conditions). For review of the role of muscle MRI in the diagnosis of the congenital myopathies and other neuromuscular conditions see references (92,93).

Serum concentrations of creatine kinase (SCK) are usually normal or only slightly elevated, particularly in those with myopathies due to dominant mutations in the skeletal muscle ryanodine receptor (*RYR1*) gene.

### 127.2.2 Muscle Biopsy

Routine hematoxylin and eosin (H&E) staining of muscle sections shows pathologic features common to most cases of congenital myopathy, but histochemical staining of fresh-frozen sections is necessary to reveal the more specific characteristics of each of the congenital myopathies (Fig. 127-2). Muscle fibers are often small, although, especially in older patients, there may be an additional population of large fibers. Replacement of muscle fibers by fat and fibrous tissue may be seen in advanced cases and occasionally at presentation, but necrotic and regenerating fibers are uncommon. Inflammation is not a typical feature. Internal nuclei may be numerous, and there may be occasional fiber splitting. Some patients with variable genetic backgrounds may show abnormal variability in fiber size, with both atrophy factors and hypertrophy factors abnormally high (94).

In addition to histologic changes, there are histochemical abnormalities that relate to the different fiber types. In a normal muscle, the histochemical differences between the two main fiber types are due to biochemical and electrophysiologic differences reflecting their functional properties. The initial distinction between type 1 (slow, oxidative) and type 2 (fast, glycolytic) fibers in congenital myopathies was drawn by Dubowitz and Pearse (95) and has served as the basis for a more detailed classification of fiber types.

The fibers of the two main types are usually of approximately equal size, but in the congenital myopathies, atrophy or hypotrophy of type 1 fibers is common (56,94,96–100). By definition, if the mean diameter of the

**FIGURE 127-2** Characteristic features of muscle biopsies in the various congenital myopathies. (A) Central core disease. (Frozen section stained with NADH,  $\times 500$ .) (B) Congenital nemaline myopathy. Nemaline bodies in subsarcolemmal location indicated by arrows. (Epoxy resin-embedded toluidine-stained section,  $\times 1200$ .) (C) Multi-minicore disease. (Frozen section stained with NADH,  $\times 300$ .) (D) Same biopsy as in (C) (Routine H&E stain with abnormality hardly detectable,  $\times 500$ .)

type 1 fibers is smaller than that of the type 2 fibers by more than 12%, (or 35–40%, as more recently proposed) (5), while the variability coefficient of the type 2 fibers (standard deviation of the fiber diameters divided by the mean of the fiber diameters) is normal (less than 0.25), selective atrophy or hypotrophy of type 1 fibers is recognized (96,101). In the absence of other diagnostic features, this is termed congenital fiber type disproportion (CFTD). It has been suggested that a predominance of type 1 fibers is also necessary for this diagnostic label to be applied,

although this may exclude some cases that are otherwise compatible with the criteria (102). The proportion of different fiber types varies in different muscles; predominance of type I fibers is defined as greater than 55% in the biceps brachii or vastus lateralis muscles (94). Predominance of type 1 fibers is a common feature of the congenital myopathies, and some patients show exclusively type 1 fibers (85,103–106). A selective smallness of type 2 fibers, on the other hand, has been reported in congenital myopathies in combination with type 1 fiber predominance (107–109),

Goebel.)

but is more often seen in other circumstances, such as for example, central hypotonia and simple disuse atrophy (94). Selective type 2 atrophy may also be a feature in congenital myasthenic syndromes (110). In the congenital myopathies, fiber types may not be well defined, but different patterns may be apparent depending on the analytic method used (111). This poor differentiation of fiber types is being explored through the study of developmental and alternative isoforms of the various proteins involved (112). Some patients with a clinical picture compatible with a congenital myopathy show only the nonspecific histologic abnormalities described earlier, with no additional more specific abnormality (113–115).

The characteristic histologic features upon which the definitions of each disorder are based are discussed under the respective subheadings. Electron microscopic studies of muscle ultrastructure are useful in confirming the diagnosis of the congenital myopathies, but immunohistochemical studies do not have the same role as in the diagnosis of the congenital muscular dystrophies.

### 127.2.3 Inheritance

Although there may be phenocopies, cases showing a typical clinical picture in combination with typical histologic features can reasonably be assumed to be caused

**FIGURE 127-2, cont'd** (I) Myofibrillar myopathy (desmin myopathy). Biopsy from a patient with a mutation in the desmin gene. Dense granulomatous material at the periphery of a fiber. (Electron micrograph by courtesy of Prof Caroline Sewry.) (J) Rod-core disease. Nemaline bodies (A) and core-like area (B) in a patient with rod-core disease caused by *KBTBD13* mutation. **TABLE 127-2** Modes of Inheritance for Congenital Myopathies, Myofibrillar Myopathies and Myosin Storage Myopathies

Myopathy	Inheritance
Myotubular (centronuclear)	X-linked, AD, AR
Nemaline (rod) myopathy	Mainly AR, less frequently AD, new dominant mutations common (ACTA1)
Actin myopathy	Mostly new dominant mutations
CCD	Mainly AD, less frequently AR
MmD	Mainly AR, rarely AD
Congenital fiber type disproportion	Sporadic, AR and AD
Myosin storage myopathy	AD, AR, often sporadic
MFM	AD, AR, often sporadic

AD, autosomal dominant; AR, autosomal recessive.

genetically. More than one mode of inheritance is known for most of the congenital myopathies (Table 127-2). The proportion of new mutations and the incidence of germ line mosaicism are uncertain. A number of genes for congenital myopathies have been identified (see Table 127-1), most of them encoding sarcomeric proteins and proteins involved in calcium homeostasis and EC coupling. With a few exceptions such as the giant nebulin gene, for most of the genes identified in the congenital myopathies to date, molecular genetic testing is now available for diagnostic purposes (116–119); this is discussed under the specific subheadings for each congenital myopathy.

Where molecular genetic analysis is not yet routine, an attempt should be made to clarify the mode of inheritance in an individual family through clinical examination of both parents, to rule out any minor muscle weakness. Muscle biopsy of the parents was previously commonly performed (120–124), and in some families, both

clinically healthy parents have shown abnormalities on muscle biopsy, suggestive of heterozygote manifestations of a recessive gene (56,125,126). Some, but not all, carriers of X-linked myotubular myopathy have abnormal biopsy findings (57,127). EMG of either or both asymptomatic parents may also show abnormalities (128–131). The interpretation of slight abnormalities on clinical examination, EMG, or muscle biopsy remains difficult. Evaluating the mode of inheritance in sporadic cases, therefore, requires great care, and all families should be provided access to genetic counseling. After the discovery of many of the causative genes, molecular genetic studies are most useful in resolving these problems and are likely to replace alternative means of parental investigation.

### 127.2.4 Diagnosis and Differential Diagnosis

The diagnosis of a congenital myopathy can be made in the presence of a typical clinical picture and typical structural abnormalities of the muscle fibers visible in muscle biopsy sections stained by histochemical methods. For an increasing number of the congenital myopathies, molecular genetic confirmation of the diagnosis is possible (Table 127-1). In view of the rarity of the congenital myopathies, it is worth concentrating diagnostic investigations at centers that have sufficient experience with clinical diagnosis and muscle pathology of neuromuscular disorders (5). Because many of the characteristic histologic abnormalities are not specific but have been encountered in a number of probably unrelated conditions (94,132–140), the diagnosis of a congenital myopathy is not justified in the absence of a typical clinical picture.

Combinations of histologic abnormalities characteristic of different congenital myopathies have been encountered within families, sometimes even in the same patient (59,100,141–144), and could recently been attributed to different genetic backgrounds. For example, the combination of nemaline bodies and central cores (“core-rod myopathy”) has been noted in a number of families (22,23,123,145–156), and has been recently attributed to mutations in the ryanodine receptor type 1 gene (*RYR1*) on chromosome 19q13 (22,23), the skeletal muscle  $\alpha$ -actin (*ACTA1*) gene on 1q42.1 (157), the cofilin-2 (*CFL2*) gene on 14q11 (158), the nebulin gene (*NEB*) on 2q21.2-q22 (159) or the *KBTBD13* gene on 15q22.31 (14). Core formation has also been noted in centronuclear myopathy, and some of these cases may be due to *RYR1* mutations (19). Myosin storage myopathy due to mutations in the *MYH7* gene (160) may resemble the core myopathies, Central Core Disease (CCD) and Multi-minicore Disease (MmD). Selcen et al. (161) described a family with cardio-neuromyopathy, histologically characterized by central hyaline masses surrounded by nemaline bodies.

Many patients with one of the other congenital myopathies also fulfill the mathematical criteria of CFTD. For example, some patients with nemaline myopathy have

shown nemaline bodies only in the second muscle biopsy (83,85,104,106,162,163), whereas the fiber type disproportion was evident in both biopsies. Patients with biopsy findings characteristic of myotubular myopathy in one biopsy have shown only nonspecific abnormalities in another (164–166). Increasingly, in patients with CFTD and no other specific features, mutations are being identified in the known genes for congenital myopathies. After the first identification of mutations in the *ACTA1* gene (38), a greater number of patients have shown either dominant mutations in *TPM3* (40) or recessive mutations in *RYR1* (41), while recessive mutations in *SEPN1* appear to be less frequent (39).

Abnormalities of the CNS may cause floppiness and predominance of type 1 fibers (167). A central cause should therefore be excluded. In cases presenting as floppy infants, the differential diagnosis includes the Prader–Willi syndrome, which causes severe hypotonia and feeding difficulties. This diagnosis can be confirmed by molecular genetic studies. Because of the clinically and histologically similar picture, the congenital form of myotonic dystrophy (see Chapter 122) needs to be excluded in all new cases suspected of X-linked myotubular myopathy prior to performing a muscle biopsy. This can preferably be done using molecular genetic methods, or, if not available, by performing EMG to exclude myotonia in the mother. The severe form of spinal muscular atrophy and other anterior horn cell disorders should also be excluded, as should congenital muscular dystrophy and the motor neuropathies (see Chapters 116, 118 and 120).

Rarely, the muscle weakness in sporadic cases has shown a scapulohumeral distribution, with terracing of the shoulders resembling severe FSHD (168–171).

In addition to mutations in beta-tropomyosin (*TPM2*) gene causing nemaline myopathy, the mutations in this gene have also been identified in distal arthrogryposis (172).

The recent identification of two nemaline myopathy families presenting with distal weakness indicates that nemaline and distal myopathy form a continuum, and that nemaline myopathy needs to be taken into account in the differential diagnosis of distal myopathies (173).

For patients in whom the initial workup reveals no specific histologic features, and no genetic cause has been identified, a later reassessment is recommended. This includes MRI of muscles to identify any selective pattern of muscle involvement to guide mutation detection, and, if this is inconclusive, a second biopsy should be performed some years after the initial muscle biopsy (5).

## 127.3 MANAGEMENT

No curative treatment is currently available for the congenital myopathies. However, much can and should be done for the patient. Management is best entrusted to a multidisciplinary team familiar with the treatment of neuromuscular disorders in the appropriate age group (174). In view of the favorable outcome documented for

some patients, active treatment is indicated initially even in the severe congenital cases (51,52,55,56,175). Because no reliable prognostic indicators have been established, we believe that judgments of how actively an infant should be treated should not be based on diagnosis as such. Any decision to refrain from active treatment needs to be taken *in casu* using the same criteria as for children with other neonatally severe conditions.

An international group of experts have suggested strategies for the assessment and treatment of respiratory insufficiency in the congenital myopathies (60). Regular monitoring of respiratory capacity is most important, especially because respiratory compromise may be out of proportion to the patient's overall muscle weakness, and special attention should be paid to possible signs of nocturnal hypoventilation and hypoxia. Thus, even in ambulant patients, the need for intermittent or permanent noninvasive mechanical ventilation should be evaluated at an early stage, because of the risk of sudden respiratory failure (53,58–60,176–179). Continuous recording of overnight pulse oximetry during sleep should be performed annually when forced vital capacity (FVC) is less than 60%, and more often when FVC is less than 40% (60). The results of treatment of patients with congenital myopathies by noninvasive mechanical ventilation are often very satisfactory because of the absence of primary lung involvement. Respiratory infections should be treated actively. Follow-up care should include the assessment of cardiac status because of the risk of cor pulmonale (58,180).

Swallowing difficulties are common and may require intervention to prevent aspiration. Conservative treatment by a speech therapist may also help toward overcoming any feeding difficulties. Early speech therapy is recommended to support normal speech development, particularly for patients with dysarthria.

Should scoliosis develop, in patients with respiratory impairment early operation is preferable to bracing because of the tendency of bracing to restrict respiration still further. The timing of surgical treatment should be before the scoliosis has become too severe and while respiratory capacity is still sufficient for such a major operation (181). Surgical stabilization of the spine may also help maintain an adequate vital capacity.

Other deformities and contractures should be treated conservatively but actively in the first instance to avoid surgical interventions requiring immobilization. Orthopedic treatment should be undertaken very selectively and only at centers with extensive experience with neuromuscular diseases, and postoperative mobilization ought to be rapid. If immobilization for other reasons (e.g. trauma) cannot be avoided, its adverse effects in terms of irreversible muscle atrophy should be counteracted by early intensive physiotherapy.

The aim of regular physiotherapy includes the preservation of muscle power and function, with emphasis on maintenance of cardiorespiratory capacity, thoracic mobility, coughing, and drainage. It is uncertain whether

specific training of inspiratory muscle function is beneficial, whereas there is more evidence supporting the use of mechanical aids for assisted coughing exercises (60). The most useful exercises for improving cardiorespiratory function are those that promote endurance, such as swimming and horseback riding (182). Other goals are the prevention of scoliosis, back pain, and contractures, and the maintenance of mobility, head control, and independence in the activities of daily living.

CCD and probably MmD secondary to mutations in patients with skeletal muscle ryanodine receptor (*RYR1*) gene, are at a greater than normal anesthetic risk of malignant hyperthermia (MH) reactions during anesthesia (183). A higher risk is not clearly associated with the other congenital myopathies, but it is necessary for the anesthetist to be aware of the patient's diagnosis and to plan the anesthesia accordingly (184–188). Careful preoperative assessment is necessary (60). Wedel (189) reviewed the association between MH and this group of disorders, suggesting that succinylcholine should generally be avoided, even in the absence of a specific contraindication. Most myopathies lead to disturbances of calcium metabolism in muscle tissue, and this condition apparently confers an increased risk of complications when succinylcholine is used for relaxation or when the volatile anesthetics are employed. More recent reviews have focused on *RYR1*-related myopathies and the potentially associated MH risk (190).

Patients should be encouraged to choose an occupation fitting their intellectual capacity, and free from physical strain, high risk of infection, and exposure to tobacco smoke and other inhaled irritants.

Many patients have gone through pregnancy and delivery without significant problems (188,191–197). However, the pregnancies of affected women should be carefully supervised, with care coordinated cooperatively by the obstetrician and neurologist, taking into account the patient's respiratory capacity, muscle weakness, and any contractures potentially complicating delivery. Although involvement of smooth muscle is not usually a feature of the congenital myopathies, the process of labor in affected women must be carefully planned and managed individually.

## 127.4 GENETIC COUNSELING

Genetic counseling should be offered to all families in which a diagnosis of a congenital myopathy has been made. Care should be taken while interpreting the mode of inheritance, especially in families with only a single affected member. Primary (i.e. in the context of genetics, phenotypic) prevention of the disorders is currently not possible.

Molecular genetic confirmation of diagnosis, mode of inheritance, and carrier status is already possible in several of the congenital myopathies, and as other causative genes are being found, counseling can and should increasingly be based on molecular genetic testing.

## 127.5 NEMALINE (ROD) MYOPATHY

Nemaline myopathy was first described in 1963 in two independent reports (198,199). The autosomal dominant forms (MIM \*161800) and the more common autosomal recessive forms (MIM \*256030) may be histologically similar. Both display clinical and genetic heterogeneity; seven genes are known to cause nemaline myopathy when mutated: nebulin (*NEB*) (200), slow skeletal muscle actin (*ACTA1*) (8), alpha-tropomyosin (*TPM3*) (9), beta-tropomyosin (*TPM2*) (12), slow troponin T (*TNNT1*) (13), cofilin-2 (*CFL2*) (158) and Kelch-repeat and BTB (POZ) domain containing 13 (*KBTBD13*) (14) (Table 127-1). Of these, nebulin and actin are the two main causative genes. Genetic linkage studies indicate that at least one further gene exists (201). All the causative genes identified to date encode proteins of the thin filament, with the exception of the latest one to be found, *KBTBD13*, the function of which remains to be clarified.

There have been a number of suggestions for subclassification of congenital nemaline myopathy (202–204). The classification by the International Consortium on Nemaline Myopathy, mainly designated for gene identification, is based on what is recognized as the typical form of nemaline myopathy, and on how other types differ from this form (205). Studies of genotype–phenotype correlations in patients with known mutations may bring about a revised classification, but currently still, a clinical classification permitting accurate prognostication or the determination of the mode of inheritance in singleton cases awaits further molecular genetic studies and genotype–phenotype correlations. Comparisons of the clinical pictures in patients with nebulin and actin mutations indicate some differences in severity and distribution of muscle weakness (206). For clinical reviews, see North et al. (74), Ryan et al. (53), Agrawal et al. (207), and Wallgren-Pettersson et al. (206).

Isolated adult-onset cases (49,208–214) differ from the other forms in the absence of dysmorphic features; in these cases, the disease often follows a clearly progressive course. The presenting feature may be so-called dropped head (215–217). In this group of patients, sporadic late-onset nemaline myopathy has been recently defined as a clinical entity. This disease has been found to be autoimmune in origin, raising the possibility of therapy using stem cell transplantation (217–221).

### 127.5.1 Special Features of Muscle Pathology

The histologic definition of nemaline myopathy is based on the presence of thread- or rod-like bodies, the nemaline (rod) bodies in the muscle fibers of patients (Greek *nema*=thread) (see Fig. 127-2B). The nemaline bodies are most readily visualized after staining with the Gömöri trichrome method, applicable to paraffin as well as fresh-frozen sections (94,222), or in toluidine blue-stained semi-thin plastic sections. Electron microscopy confirms the lattice

structure of the nemaline bodies. These are derivatives of the Z disk and the thin filament,  $\alpha$ -actinin being a main constituent. Nemaline bodies are also labeled with antibodies against myotilin and telethonin and associated with them are also actin, tropomyosin, and desmin (223–228). There is often a deficiency of either or both subtypes of the fast, type 2 muscle fibers (106), and often the exact fiber types may be difficult to define histochemically (205). No histologic means of definitively distinguishing between the various forms of nemaline myopathy has yet been found, although specific histologic features, if present, may be helpful in some cases in directing molecular genetic studies (5,162,229–231). (For reviews, see References (5,74,206).)

Some cases have shown intranuclear nemaline bodies, with or without sarcoplasmic nemaline bodies (for review, see references (232) and (233)). A number of these patients have been found to have mutations in the skeletal muscle  $\alpha$ -actin gene (*ACTA1*) (8,234).

A pathogenetic relationship between nemaline myopathy and congenital myopathy with excess of thin filaments (233) was established through the findings of mutations in the actin gene in both groups of patients (234).

It is to be noted that in the typical autosomal recessive form of nemaline myopathy, even heterozygote carriers may show deficiency of type 2B muscle fibers (61).

Nemaline bodies are not pathognomonic for congenital nemaline myopathy but have been described in combination with features of other myopathies (see Section 127.2.4), and in a number of contexts probably unrelated to muscle disease. These include patients with acute psychosis (134), patients who have undergone radiotherapy for cancer (235–237), patients undergoing hemodialysis (136), and animal muscle after tenotomy (137,238,239). They also occur normally in extraocular muscles (240), myotendinous junctions (241), and in the muscles of aged persons (242). Therefore, it is not justified to make the diagnosis of hereditary nemaline myopathy without a typical clinical picture.

Nemaline bodies in patients with human immunodeficiency virus infection have usually been regarded as epiphenomena, but in some cases, they have been associated with myopathy (138,243–248). One patient treated for dermatomyositis was examined because of lacking response to treatment and was found to have nemaline bodies (249). Cases of nemaline myopathy have been reported with mitochondrial abnormalities (250–255).

Yet another pathological pattern is exemplified by a sib pair with cardioneuromyopathy showing histologically characteristic central hyaline masses surrounded by nemaline bodies (161).

### 127.5.2 Clinical Characteristics

In the typical autosomal recessive form, most often caused by nebulin mutations, the patients commonly have a nasal voice or even dysarthria, the palatal reflex is usually absent, and most patients are unable to lift

their heads in the supine position (56,201). The weakness is more pronounced in the axial muscles and the limb girdles than in the proximal limb muscles. A definite distal involvement, including foot drop, may be noted later in addition to the proximal muscle weakness; this may be confused clinically with the peroneal paresis of a peripheral neuropathy, or with the distal myopathies. In fact, recently, nemaline myopathy has been shown occasionally to present with distal weakness (173). The tongue often becomes relatively small and furrowed. The facial and bulbar muscles are weak, but the extraocular muscles are spared. A skew toward higher levels of intelligence has been noted in one small series of individuals with nemaline myopathy (56).

Respiratory problems are a common feature of congenital nemaline myopathy, not only in the neonatal period, but also throughout life, and may be the presenting feature (157). Respiratory infections are common, especially from birth to school age, and should be treated vigorously but may subside with time (53). Although they are symptom free, most patients, including ambulant ones, will show restriction of their respiratory capacity on testing. The patients run a great risk of insidious nocturnal hypoxia, even in the absence of morning symptoms, and several patients have experienced sudden respiratory failure (53,56,58,59,256–259). Continuous monitoring of respiratory capacity and early employment of mechanical ventilation at night and, if required, intermittently during the daytime is therefore recommended (60,260). Freedom from hypoxia is vital for the patient's quality of life and for avoiding complications such as cor pulmonale. Strategies have been outlined for ventilatory support in the congenital myopathies (60).

Cardiac contractility is usually normal in congenital nemaline myopathy (261). Although cardiac involvement has been reported in some cases showing nemaline bodies in skeletal or cardiac muscles (262–270), only two cases appear indistinguishable from congenital nemaline myopathy, and in addition, show childhood onset of histologically verified dilated cardiomyopathy with nemaline bodies (262,263). Furthermore, nemaline bodies have been observed in developing cardiac hypertrophy in patients with no clinical evidence of cardiomyopathy and with no disease of the skeletal muscles (271). Post-mortem investigations have in most cases not revealed nemaline bodies in heart muscle (69,72,73).

To our knowledge, there have been no reports of MH in congenital nemaline myopathy, although one report describes three children with nemaline myopathy in whom the heart rate decreased during induction of anesthesia for cardiac surgery, and body temperature increased during or after surgery (272). Thus, although patients with nemaline myopathy are not regarded as being at risk for MH, the anesthetist needs to be aware of the patient's muscle disorder and take precautions accordingly (185,187,188,273). This may be especially important in cases with unknown cause of the disease.

Fetal akinesia sequence has been postulated as an entity within the nemaline myopathies (44,274,275, 276), in addition to previous descriptions of arthrogryotic cases (277–279).

The International Consortium on Nemaline Myopathy has defined six clinical categories of nemaline myopathy, based on knowledge of the typical form and how some groups of patients differ from those with that form: (1) the severe congenital form, with patients lacking spontaneous movements or respiration at birth, or with fractures or severe contractures at birth; (2) the intermediate congenital form, with patients moving and breathing at birth but who are later unable to achieve ambulation or respiratory independence; (3) the typical congenital form, with typical distribution of muscle weakness, milestones delayed but reached, and slowly progressive or nonprogressive course; (4) mild nemaline myopathy with childhood onset; (5) adult-onset nemaline myopathy; and (6) other forms of nemaline myopathy with unusual associated features (205).

Adult-onset cases are heterogeneous and most are unlikely to be genetic in origin. The recently defined sporadic late-onset nemaline myopathy (SLONM) (217–221,280) with subacute presentation after the third decade may show gammopathy, degeneration and a relentlessly progressive course (209,281–285), while patients without gammopathy appear to have a better prognosis (217). Recently, successful treatment for SLONM has been reported using stem cell transplantation or immunoglobulin (217–221,280). Some cases present with respiratory failure without any noted preceding muscle weakness (286–288), while others present with “dropped head” (215,216,289) or camptocormia (290).

### 127.5.3 Modes of Inheritance and Genotype–Phenotype Correlations

In familial cases of nemaline myopathy, autosomal recessive inheritance is more common than autosomal dominant inheritance (61,201). Autosomal recessive nemaline myopathy is most commonly caused by mutations in the *nebulin* gene, *NEB* (6–8,200,206,291,292). Deletion of exon 55 is a founder mutation with worldwide occurrence in the Ashkenazi Jewish population, the reported carrier frequency being 1:108–1:168 (293). Rarer causes of recessively inherited nemaline myopathy include mutations in the slow skeletal alpha-actin gene, *ACTA1* (8,158,206,207,294), the genes for beta- or alpha-tropomyosin, *TPM2* and *TPM3*, troponin T1, *TNNT1*, or cofilin-2, *CFL2* (11,158,295). Recessive mutations identified in *ACTA1* are genetic or functional null mutations causing severe myopathy (296). These patients retain expression of cardiac actin in their skeletal muscles and the muscle fibers may also show zebra bodies. In *TPM3*, a homozygous deletion, a likely founder mutation has been identified in the Turkish population (297).

Autosomal dominant nemaline myopathy is often caused by mutations in the actin gene *ACTA1* (8,53,298,299) but may also be caused by mutations in *TPM2* or *TPM3* (9,10,12,300–302). In the first family to be described, an Australian family with a dominant *TPM3* mutation, weakness was most pronounced in the lower limbs (9,10), but subsequent descriptions have shown that this is not consistent (301,303). Fiber type distribution varies, but nemaline bodies may be present in type 1 fibers only. A small number of families have been described with dominant mutations in *TPM2* (12). Dominantly inherited nemaline myopathy caused by mutations in the *ACTA1* gene may be slightly more common, but even these cases fail to show consistent differences compared with the recessively caused cases and there is variability even within families (8,207,294,299,304). A peculiar form of muscle slowness, with inability to correct body position to avoid falls, has been described in two-thirds of families showing linkage to the chromosome region 15q, with a myopathy featuring onset of weakness in early childhood and the presence in the muscle fibers of both nemaline bodies and core-like formations (148,305–308). This form of dominantly inherited nemaline myopathy has recently been shown to be due to mutations in the gene *KBTBD13* (14).

Sporadic cases are often caused either by new dominant mutations in *ACTA1* (8,207,234,294,298,309,310) or by two recessive nebulin mutations (292). Thus, it is worth testing first for mutations in *ACTA1*, because this is a small gene of six coding exons, and testing is available as a service. Molecular genetic confirmation of the diagnosis in nemaline myopathy caused by mutations in the other major gene, nebulin, still poses a problem because of the size of the gene. It comprises 249kb of genomic sequence and 183 exons (311). Mutation analysis of the other small genes is thus recommended before embarking on nebulin testing.

In addition to the above-mentioned seven genes, at least an eighth gene is postulated for nemaline myopathy (201,312), and candidates are being explored among the genes for thin filament proteins and the Z disk (313).

Genotype–phenotype correlations among families in which mutations have been identified are slowly emerging, but appear complicated (205,206,292,314–318). A locus-specific mutational database has been established for mutations in *ACTA1* (<http://waimr.uwa.edu.au>), in which no missense polymorphisms have been reported. A similar database for *NEB* is under way ([http://www.dmd.nl/nmdb2/variants.php?action=search\\_unique](http://www.dmd.nl/nmdb2/variants.php?action=search_unique)). In addition to nemaline myopathy, mutations in *ACTA1* can cause intranuclear rod myopathy (8,234,319–321), actin filament aggregate myopathy (8), congenital fiber type disproportion without nemaline bodies (38), myopathy with core-like areas (322), and cap disease (323). *NEB* mutations may cause distal nebulin myopathy, core-rod myopathy and nemaline myopathy with a distal presentation (159,173,324).

A detailed study of 60 patients with mutation of one of the two most common causative genes, *ACTA1* and *NEB*, showed some differences in clinical severity and in the distribution of muscle weakness (206,314), corroborated by comparisons of muscle MRI results of patients with mutations in the same genes (90,91). Severe nemaline myopathy is more often caused by *ACTA1* mutations. In both groups of patients, muscle weakness was generalized, usually symmetric, and most pronounced in the neck flexors. In patients with *NEB* mutations, the ankle dorsiflexors were also very weak, whereas the extensors of the knees were well preserved in comparison with the knee flexors. In patients with *ACTA1* mutations, the knee extensors were weaker than the flexors, and there was better preservation of the ankle dorsiflexors.

In some cases, histologic findings may direct mutation detection. If the muscle biopsy shows uneven staining for nebulin, a nebulin mutation is probably more likely than an *ACTA1* mutation (200,229,230), and if there are intranuclear nemaline bodies, an excess of thin filaments, retained expression of cardiac actin in muscle or zebra bodies, an *ACTA1* mutation is likely (8,316). In patients with both fast and slow muscle fibers present, more severely affected type 1 fibers and normal-appearing type 2 fibers may be a clue to a mutation in *TPM3*, not expressed in fast fibers (297,301,325). Core-rod myopathy may be caused by mutations in *RYR1* (22,23), *ACTA1* (157), *CFL-2* or in *KBTBD13* (14,148,158,305).

The typical form of nemaline myopathy (56,205) is usually due to mutations in *NEB* (6,7,200,291), but sometimes to new dominant mutations in *ACTA1* or *TPM2* (206,294,298).

In families with severe nemaline myopathy, mutations have often been identified in *ACTA1* (8,207,294,298,326) and, more rarely, in *NEB* (327). In a small number of families with *ACTA1* mutations, one parent showed somatic mosaicism for the mutation, a phenomenon not hitherto encountered in families with mutations in *NEB*. This needs to be taken into account in genetic counseling. Somatic mosaicism has been observed in two out of nearly 80 families in total in which *ACTA1* mutations have been identified (294). Moreover, an instance of gonadal mosaicism has been observed (Professor Nigel G. Laing, personal communication). The intermediate form may be caused by mutations in *TPM3* (295), *ACTA1* (206,294,315) or *NEB* (206,292). Some of the patients with recessive mutations in *ACTA1* have a milder myopathy than those with heterozygous mutations (316).

Mild nemaline myopathy has been caused by mutations in *ACTA1*, *NEB*, *TPM2*, *TPM3* or *KBTBD13* (14,206). Many of the patients with mutations in *KBTBD13* show a distinct slowness of movements (14,148,305–308).

A homozygous nonsense mutation in the slow tropomyosin T gene (*TNNT1*) causes an autosomal recessive form of nemaline myopathy in children of the Old Order Amish

community (13,328). Special features of this nemaline myopathy are tremor and progressive contractures.

The two patients reported with homozygous mutations in *CFL-2* differed from patients with the typical congenital form of nemaline myopathy in lacking facial weakness and foot drop (158).

#### 127.5.4 Pathogenetic Considerations

The pathogenetic mechanisms leading from mutation to nemaline myopathy are becoming discernible through functional studies of the implicated genes and their sarcomeric proteins. Models under study include mouse models (275,329–337), spontaneously occurring myopathies in animals (338–340), *Drosophila* models (341–343), baculovirus expression systems (343), tissue culture models, and functional, physiological and direct visualization studies of normal and altered proteins (16,275,276,311,320,321,325,344–358).

Mutations in the actin gene causing nemaline myopathy are mostly missense mutations, and they are spread all across the six coding exons (294). They are usually dominant mutations arising *de novo*, with dominant-negative effects (344,345). No missense polymorphisms have been identified (296). A mouse model has been generated for dominant *ACTA1* nemaline myopathy, confirming the observations in patients that the mutant protein load determines disease severity (332). The muscle fibers of these mice have lower calcium sensitivity than normal mice.

Patients with recessive mutations in *ACTA1* usually have no functional skeletal actin, and the severity of their disease is related to the proportion of retained expression of cardiac actin in their skeletal muscles (207,316). Normally, the expression of cardiac actin, predominating in skeletal muscle in early development, is later replaced by skeletal actin, while cardiac actin is the predominating form of actin present in the adult human heart (359). This explains why mutations in *ACTA1* do not, as a rule, cause cardiac involvement.

Because of the spectrum of different disease mechanisms caused by *ACTA1* mutations (16,296,320,321,342,350–352), it has been suggested that future therapies should be targeted toward a method that would be independent of the function of skeletal muscle actin (315). A mouse model has been generated to test the hypothesis that upregulation of cardiac actin may alleviate the myopathy caused by mutations in *ACTA1* (8,207,360). The results are very promising, with the skeletal actin knockout mice living into adulthood with good muscle strength. This leads on to the question of how this could be utilized for therapy in human patients. Increasing the proportion of normal skeletal actin in heterozygous patients is another possibility to explore further (332).

Mutations in the nebulin gene causing nemaline myopathy have been identified along the length of this enormous gene (291,292,311). All mutations published

to date have been recessive (7,200,291). Despite the fact that most of the mutations are truncating, the patients surprisingly express the C-terminus of the protein (200,229,230), and severe cases are rare. This may be explained by differential expression of the numerous isoforms of nebulin (311). Nebulin plays roles in specifying thin filament length, stabilizing and activating the filaments, as well as in ensuring force generation and efficiency of contraction (354–356). Based on the few mutations that have been studied in detail in terms of their effects, pathogenetic mechanisms leading to muscle weakness include dysregulation of thin filament length and cross bridge kinetics (355,361–363). The recently generated *NEB* knockout mouse models showing muscle weakness, but not consistently forming nemaline bodies (335,337), are contributing to the understanding of nebulin's role in the muscle sarcomere. The knockout mice have shorter thin filament lengths than normal mice and indicate roles for nebulin in capping thin filaments, in maintaining contractility and force generation and in stabilizing sarcomere structure, including Z disk structure and myofibrillar alignment (333,334). Interestingly, studies of the diaphragm muscle of the mice, a muscle severely affected in nemaline myopathy patients, show that myofibrillar disorganization begins to appear when the mice start using this muscle for breathing (335). These mouse models, however, being devoid of nebulin, and showing early lethality, mirror the human disease only to a limited extent. Since no human patients with mutations causing total absence of nebulin have been reported, it has been thought that null mutations in *NEB* would be lethal. It is thus remarkable that the knockout mice do form sarcomeres despite the absence of nebulin, indicating that nebulin is not required for myofibrillogenesis.

The mouse models with mutations in the *TPM3* and *ACTA1* genes have muscle weakness and show nemaline bodies in their muscle fibers (329–332,360). The onset of muscle weakness in the *TPM3* mouse, caused at least partially by hypotrophy of type 1 fibers, appears to be delayed by compensatory hypertrophy of type 2 fibers (329). Previous observations of immobilization having adverse effects on muscle volume and strength in nemaline myopathy (56) are corroborated by studies of the mice, which appear to benefit from postimmobilization endurance exercise (330,331). The mechanisms of muscle repair differ from those in normal mice, not exhibiting the classic features of regeneration (330,364). This is in accordance with what is known from follow-up biopsies in humans with nemaline myopathy, indicating an active disease process with segmental degeneration, reinnervation and regeneration (56,80,106). The quantity of nemaline bodies in the mice correlated with weakness, but this has not been the case in studies of patients (69,106,125,162,298). The mice showed cytoplasmic bodies also, which can indeed sometimes be found in patients with nemaline myopathy (144,329).

Missense mutations in *TPM2* appear to affect contractility of muscle fibers in a mutation-dependent way (347,349). Studies on animal models are needed to explore the recent suggestion that calcium sensitizers might have beneficial effects on single muscle fibers expressing tropomyosin altered by *TPM2* mutations (349). Mutation of *TPM2* causing absence of  $\beta$ -tropomyosin was found to underlie Escobar syndrome associated with nemaline myopathy (365).

Mutations in *TPM3* have been thought to cause nemaline myopathy by altering the stoichiometry and interrelations of tropomyosin dimers and their affinity for binding partners (325,346). Recent studies of five patients with *TPM3* mutations indicate that the contractile dysfunction is due to impaired cross bridge cycling kinetics, partly compensated by enhanced calcium sensitivity of force generation (362).

The truncating mutation in *TNNT1* causing nemaline myopathy with early respiratory failure in the Old Order Amish leads to the absence of slow skeletal muscle troponin T, and it has been suggested that upregulation of cardiac or embryonic troponin might be a therapeutic possibility (366,367), similarly to cardiac actin compensating for the loss of normal slow skeletal actin in *ACTA1*-caused nemaline myopathy.

The literature on management and therapy is scarce (5,368–370). The apparently beneficial effects a limited clinical trial of dietary tyrosine supplementation (369) warrants further study.

### 127.5.5 Actin Myopathy, Actin-Related Myopathies, Core-Rod Myopathy, Cap Myopathy, and Other Myopathies Within the Nemaline Myopathy Spectrum Caused by Mutations in Known Nemaline Myopathy Genes

In some patients with nemaline myopathy, a histologic finding in addition to that of intranuclear or cytoplasmic nemaline bodies is accumulation of excess thin filaments, the main constituent of which is actin (MIM 102610) (233). Another group of patients shows actin filament aggregation only. Mutations have been identified in the  $\alpha$ -actin gene in both groups of patients (8) and, interestingly, the mutations causing actin myopathy without nemaline bodies (294) and those causing intranuclear rod myopathy (315) tend to be clustered in particular parts of the gene corresponding to a sterically defined region of the actin protein. A recent study indicated that in intranuclear rod myopathy, the rods are formed within the nucleus (320,321). These cases often, but not always (371) carry a bad prognosis. One patient with mutation of *ACTA1* had extramuscular involvement including osteosclerosis (372). Zebra bodies and retained expression of cardiac actin have been identified in patients with *ACTA1* null mutations causing severe nemaline myopathy (316).

Moreover, mutations in the actin gene can cause CFTD with no additional specific features (38,373), also caused by *TPM3* mutations (40), or a myopathy with cores only (322).

*NEB* mutations may cause core-rod myopathy (159) as well as distal nemalin myopathy, with only distal weakness and the absence or inconspicuous presence of nemaline bodies (324). The recent identification of two families with distal presentation and nemaline bodies in their muscle fibers indicates that nemaline and distal myopathy form a continuum (173).

Cap myopathy may overlap with nemaline myopathy both clinically and histologically, some cases showing caps only (374). Causative genes include *TPM2* and *TPM3* (302,375,376), with evidence for a dominant-negative effect of one of the *TPM3* mutations identified (377).

Mutation of *TPM2* has been reported to cause dominant distal arthrogryposis (172,378) while a homozygous null allele leading to the absence of  $\beta$ -tropomyosin caused Escobar syndrome associated with nemaline myopathy (365).

## 127.6 MYOTUBULAR (CENTRONUCLEAR) MYOPATHIES

Myotubular myopathy (MTM) (or centronuclear myopathy, CNM) first described in 1966 (379), exists in all three Mendelian forms. The X-linked form (XLMTM) is the best characterized (MIM \*310400) (380) (55,238,381,382), and has been attributed to mutations in the myotubularin (*MTM1*) gene on chromosome Xq28 (15,383). Diagnostic criteria for this disorder have been outlined by the International Consortium for Myotubular Myopathy (384). The autosomal-dominant (MIM \*160150) (380) form has been associated with mutations in the dynamin 2 (*DNM2*) gene (17) while mutations in the amphiphysin 2 (*BIN1*) gene (18) and the skeletal muscle ryanodine receptor (*RYR1*) gene (19) have been implicated in autosomal-recessive forms of CNM (MIM 255200) (380). For an overview of different forms of CNM see references (385,386).

### 127.6.1 Special Features of Muscle Pathology

Histologically, the three forms of myotubular myopathy share similar features, with small muscle fibers showing a central area devoid of myofibrils and mitochondrial aggregates around the centrally located, often large nuclei (see Fig. 127-2E). Histopathological appearance at presentation may be nonspecific (387). The name “myotubular myopathy” derives from the resemblance of these fibers to normal muscle myotubes during fetal development, but in contrast to earlier suggestions (112,384,388–392) fibers do appear to mature over time (112) and the term “centronuclear myopathy” is often preferred, particularly for autosomal forms. Although strictly centralized

nuclei are more common than multiple internalized nuclei in the *MTM1* and *DNM2*-related forms (393), the opposite applies to *RYR1*-related cases (19). A radial distribution of sarcoplasmic strands on NADH staining has been reported in autosomal cases (394) and seems to be a specific feature of the late-onset form related to mutations in the dynamin 2 (*DNM2*) gene (17); the latter may also exhibit almost dystrophic features (395). Cores in addition to the myotube-like fibers may evolve over time in the *RYR1*-related form (116,396) but have also been reported in *DNM2*-related cases (397) and mildly affected patients harboring *MTM1* mutations (398,399). “Necklace” fibers may be an additional feature in various forms of CNM (398,399).

### 127.6.2 Clinical Characteristics

In addition to the features typical of all the congenital myopathies, the myotubular myopathies frequently cause ophthalmoplegia. Clinical differences between the X-linked and autosomal forms of myotubular myopathy are quantitative rather than qualitative. The X-linked form XLMTM is the most severe and has the earliest onset, the autosomal recessive form is intermediate in both respects, and the autosomal dominant form mostly has a later onset and a milder course than the other two (394). (For review, see also References (385,386).) Cardiomyopathy has been described in two sporadic cases in which mutation analysis of the *MTM1* gene was not performed (400,401). Malignant hyperthermia has been reported in a patient with adult-onset, genetically unresolved CNM (402).

### 127.6.3 Genetic Background

Identification of mutations in the myotubularin (*MTM1*) gene (15) in XLMTM, the dynamin 2 (*DNM2*) (17) gene in autosomal-dominant CNM and the amphiphysin 2 (*BIN1*) (18) and the skeletal muscle ryanodine receptor (*RYR1*) gene (19), respectively, in autosomal-recessive CNM have permitted mutation detection and confirmation of the mode of inheritance (15,383). A proportion of cases remain currently genetically unresolved.

In XLMTM, some carriers will show histologic abnormalities, and some have muscle weakness on examination (119), but it is uncertain whether similar manifestations occur in heterozygotes for the autosomal recessive genes (394) or in subclinical cases of the autosomal dominant form. Furthermore, the proportion of sporadic cases caused by new mutations remains to be determined for the genes more recently implicated in CNM.

Because the clinical differences between the autosomal and the X-linked forms are quantitative rather than qualitative, in all new (and in particular, sporadic and male) cases of CNM, it is worth checking for mutations in the *MTM1* gene in the first instance, also considering the relatively small size of the gene. Female cases may

be due to a *MTM1* gene defect in combination with a chromosomal rearrangement or skewed X-inactivation (119,403–408). If a mutation cannot be detected in the *MTM1* gene, depending on clinical and pathological presentation, either unusual *MTM1* variants (409) or mutations in one of the autosomal genes associated with CNM ought to be considered. Myotonic dystrophy is an important differential diagnosis for all forms of CNM and should be considered early in the diagnostic process.

### 127.6.4 X-Linked Recessive Form

The X-linked form commonly has its onset in utero, and the pregnancy is often complicated by polyhydramnios, (55,57,114,127,132,381,382,384,410–414) a feature rarely seen in the other congenital myopathies. The family history often includes miscarriages and male neonatal deaths in the maternal line (415) but there may be marked phenotypical variability even within the same family (416). Many affected infants lack spontaneous antigravity movements, and some fail to establish spontaneous respiration at birth (417). Contractures of the hips and knees are commonly present. Affected boys are often long, with low birthweight (418) and large head, and many show ophthalmoplegia. EMG may be normal, or “myopathic,” or may show abnormal spontaneous activity (76). Neuromuscular junction abnormalities and/or an associated neuromuscular transmission defect have been reported in XLMTM and other forms of CNM (81,419). The disease usually, but not invariably, follows a fatal course over days or weeks. Other patients may be mildly affected from the neonatal period onward with little residual disability (51,55,57,417,420–422). However, treatment policies may influence survival as much as the underlying mutation: A study from the United States (423), where treatment policies are active, reported 26 of 35 male patients surviving for at least 1 year. However, about 60% of these patients aged 1–27 years were completely ventilator-dependent, and some showed associated medical problems related to organs other than muscle, such as pyloric stenosis, gallstones, and liver hemorrhage, although those features are not universally observed in adult survivors (51,420,422).

Some female carriers of the X-linked form have slight muscle weakness on examination (119,132,424), and a few have been reported as being overtly manifesting due to skewed X-inactivation (119,404–408) or abnormalities of the X chromosome (403). Manifestation in female carriers of XLMTM may be very late in life (425). Muscle biopsy studies of obligate female carriers indicate that about one-half of carriers may have specific abnormalities on muscle biopsy, but a normal biopsy does not exclude the risk of being a carrier (57,127). Carrier status is best determined by molecular genetic methods.

Muscle biopsies of boys with the X-linked form of myotubular myopathy have been reported to show

abnormal persistence of the proteins desmin and vimentin (391,392), but this is not a consistent feature (112,426) and does probably not distinguish XLMTM from autosomal forms of CNM (427,428).

Following initial studies linking XLMTM to proximal Xq28 (403,429–436) causative mutations in the myotubularin (*MTM1*) gene at this locus were subsequently identified (15,383,417,437,438). It is to be noted that the previous indication of genetic locus heterogeneity in X-linked myotubular myopathy (439,440) was later refuted (440); the failure to identify causative mutations in affected males with typical clinical features may be due to the presence of unusual *MTM1* mutations (409).

The *MTM1* gene encodes four active sites, and mutations have been identified in all of these (116). Although *MTM1* mutations are spread across the length of the gene, exons 12, 8, and 14 are more commonly mutated than the others, harboring about 50% of mutations, whereas seven mutations account for about 25% of cases (116,118,438,441–446). Approximately 30% are missense mutations affecting conserved residues (116,441). Some deep intronic mutations may not be detectable on routine sequencing (409). Molecular genetic confirmation of diagnosis, determination of carrier status, and prenatal diagnosis are available as a routine service (116–119). New mutations in affected male patients are not as common as previously thought (441); a majority of mothers of affected boys will be found to be carriers (116). At least five instances of mosaicism have been documented (441,447,448), so that, even in cases in which the mutation detected in an affected son has not been found in the mother's lymphocyte DNA, the parents might want to consider prenatal mutation testing of male fetuses in subsequent pregnancies.

No strong correlation appears to exist between clinical severity and the nature of the mutation; severity varies even within families. Two boys with myotubular myopathy and intersexual genitalia had a deletion extending beyond the myotubularin gene (449). An extensive study addressing genotype–phenotype correlations (417) indicated that some nontruncating mutations are associated with a milder clinical course (see also references (51,420,422)), whereas other nontruncating mutations and all known truncating ones are associated with the common, neonatally very severe form.

### 127.6.5 Autosomal Dominant Form

A substantial number of families compatible with autosomal-dominant inheritance have been reported in the premolecular era (57,168,394,427,450–462) and a proportion of cases have now been attributed to mutations in the dynamin 2 (*DNM2*) gene (17,393,463–466).

Typical *DNM2*-related CNM is a relatively mild condition but severity varies widely, with onset from birth to the fifth decade (463,467). Even the most severe cases with neonatal onset may show improvement over time

(463,468), provided respiratory complications are managed proactively as those may be fatal if left untreated (21). Facial weakness, ptosis and ophthalmoplegia are common. Muscle weakness is often predominantly proximal, but many patients show additional truncal and distal involvement (395,397). Marked muscle hypertrophy, particularly affecting the calves, has been reported in some patients (399). *DNM2*-related CNM is allelic to a form of dominant intermediate Charcot–Marie–Tooth disease (CMTDIB) (469) and occasional, subtle signs of peripheral or central nervous system involvement also reported in *DNM2*-related CNM suggest a continuum between the two entities in some patients (393,464,467). As in CMTDIB patients, non-muscular features such as neutropenia (399) or cataracts (21) may also be observed in a subgroup of patients with *DNM2*-related CNM. Muscle MRI shows a pattern of selective muscle involvement distinct from congenital myopathies with other genetic backgrounds (395,397,465).

In addition to the histopathological features shared by all forms of CNM, late-onset *DNM2*-related CNM typically features additional radial strands (17), and almost dystrophic features as well as core-like structures are not uncommon (395,397). “Necklace” fibers may be observed (399) but are not specific. In contrast to the *RYR1*-related form and in common with XLMTM, strictly centralized nuclei are more common than multiple and internalized nuclei (393).

Mutations affecting the *DNM2* middle domain are usually associated with milder presentations (17), whereas those concerning the pleckstrin homology domain give rise to more severe forms with earlier onset (21,395,463).

### 127.6.6 Autosomal Recessive Form

Autosomal recessive inheritance of CNM has been reported in the premolecular era in a number of families with suggestive clinical and pathological features (57,70,124,130,142,394,470–474) and has been recently attributed to mutations in the amphiphysin 2 (*BIN1*) (18) and the skeletal muscle ryanodine receptor (*RYR1*) (19) gene. In both forms age at onset is mostly in infancy or early childhood and ophthalmoplegia, ptosis, and facial weakness are common clinical features.

*BIN1*-related CNM has been reported only in few families to date (18,475–477) mainly associated with early onset and a severe phenotype, which may feature associated respiratory impairment and may result in loss of ambulation (477). Marked intrafamilial variability and associated mental retardation has been reported in one consanguineous family (475).

Mutations in the skeletal muscle ryanodine receptor (*RYR1*) gene, one of the more common causes of inherited neuromuscular disorders (see below), have been reported as another and probably relatively common cause of congenital myopathies with central nuclei (19,478).

Clinically, *RYR1*-related CNM is typically of early onset and moderate severity with improvement over time but may occasionally mimic the appearance of XLMTM in males. Ptosis and extraocular muscle involvement are common. Bulbar involvement requiring nasogastric tube feeds and respiratory impairment needing ventilatory support are often transient but a permanent ventilatory requirement has been reported in the most severe cases. On the histopathological level, multiple internalized nuclei in addition to typical centralized nuclei are common and core-like structures more suggestive of *RYR1* involvement may evolve over time (19,478). Associated congenital fiber type disproportion, another *RYR1*-associated histopathological feature (41), may be prominent. *RYR1*-related congenital myopathy with central nuclei is often associated with compound heterozygosity for *RYR1* missense mutations and *RYR1* mutations resulting in low abundance of functional RyR1 protein (19), corresponding to the situation in other recessively inherited *RYR1*-related myopathies (25,479). There appear to be no mutational hotspots. Some *RYR1* mutations may not be detectable on routine sequencing (480), probably explaining the substantial proportion of cases with presumably recessive inheritance but only one heterozygous missense mutation identified, either inherited from an asymptomatic parent or of de novo occurrence (396). *RYR1*-related CNM is common in the South African population due to the presence of multiple founder effects (19).

There is likely to be further heterogeneity. Tosch et al. reported two CNM patients with missense variations in the novel phosphoinositide phosphatase (hJUMPY), in one patient associated with a de novo mutation in the *DNM2* gene. The inheritance in these families is uncertain but could be either recessive with an undetected second allele, or digenic (481).

### 127.6.7 Pathogenetic Considerations

Most of the genes implicated in various forms of CNM to date, namely *MTM1*, *DNM2* and *BIN1*, encode proteins involved in various aspects of membrane trafficking (for review, (482)) and endocytosis. Alterations of skeletal muscle ryanodine receptor (RyR1) assembly and function have more recently emerged as an important pathogenetic mechanism in CNM, both primary and secondary, the latter mediated through indirect effects of *MTM1*, *DNM2* and *BIN1* mutations on the assembly of the EC machinery (483).

*Myotubularin* belongs to the large family of dual-specificity phosphatases that play a role in the epigenetic regulation of signaling pathways involved in growth and differentiation (for review see references (484,485)). There are homologs of myotubularin in many species, including mice and yeast, as well as many human homologs (15,441,486–489), some of them found to be mutated in distinct forms of Charcot–Marie–Tooth

disease (490–493). A specific function has been proposed for myotubularin in dephosphorylating phosphatidylinositol 3-phosphate (PtdIns3P), a lipid second messenger with a crucial role in membrane trafficking (383,494–505). In addition to the catalytic site, myotubularins contain lipid and protein binding sites and form homo- and heterodimers, in which active and inactive protein binding to each other may produce conformational changes affecting substrate affinity, hydrolysis, and binding to associated proteins (502,506–508). More recently, secondary effects have been reported of loss of myotubularin on T-tubule assembly (509), endosomes (510) as well as desmin intermediate filament architecture and mitochondrial dynamics (511,512). The deleterious effect of specific *MTM1* mutations may thus be due to destabilization of the three-dimensional structure, loss of enzymatic activity or disturbed protein–protein interactions (513). Findings in a myotubularin knockout mouse model (514) suggest that myotubularin is necessary for the maintenance of muscle fibers but not for myogenesis, and that the myotubularin-deficient phenotype may be correctable by delivery of the functional protein through viral vectors (515) or other therapeutic interventions (516).

Mutations in the *dynamamin 2* (*DNM2*) gene have been shown to disturb specific enzymatic functions (517), dimerization of the mutant protein (518) and endocytosis pathways (519). A knock-in mouse model of the common *DNM2* R465W mutation (520) exhibits impaired skeletal muscle structure and function, with specific evidence of increased intracellular calcium and dysferlin accumulation. Disturbed reticular assembly and secondary mitochondrial alterations are a feature in the mouse model and have also been reported in humans (521). (For review of dynamamin 2 physiology and pathophysiology see reference (522).)

Mutations in the *BIN1* gene encoding *amphiphysin 2* have been demonstrated to abolish interactions with dynamamin 2 and to disrupt the membrane tubulation properties of the mutant protein (18), corresponding to the important role of the functional protein in T-tubule biogenesis (523).

An autosomal form of CNM in Labrador retriever dogs has been attributed to dominant mutations in the *PTPLA* gene and may provide a model for currently genetically unresolved forms of the condition in humans.

## 127.7 THE “CORE MYOPATHIES”: CCD AND MMD

Core myopathies are a clinically and genetically heterogeneous group of congenital myopathies with the common defining histopathological feature of focally low oxidative activity on muscle biopsy (for review see references (524,525)). The variability of oxidative stain abnormalities is reflected in the wide range of descriptive terms (“central

cores, minicores, multicores, multi-minicores”) applied to these conditions and has provided the basis for the designation of histopathologically defined entities, namely central core disease (CCD) and multi-minicore disease (MmD). Recent years have seen major advances in the genetic resolution of the core myopathies, with mutations in genes encoding proteins involved in calcium homeostasis and EC coupling, namely the skeletal muscle ryanodine receptor (*RYR1*) and the selenoprotein N (*SEPN1*) gene, being the most common identifiable causes. Congenital myopathies with cores on muscle biopsy have been less frequently reported in genetically distinct forms, often associated with clinico-pathological features unusual in the context of the more common genetic backgrounds. The process from the histopathological diagnosis of a core myopathy to the identification of a specific genetic defect is complex and ought to be informed by a combined appraisal of histopathological, clinical and, increasingly, muscle MRI data in a multidisciplinary setting.

### 127.7.1 Central Core Disease

In 1956, Magee and Shy (526) reported a family where five individuals over three generations were affected by congenital, nonprogressive hypotonia and weakness, sometimes with prenatal onset. Muscle biopsy in the affected members of this family showed amorphous central areas within almost every muscle fiber stained with the modified Gömöri trichrome technique.

The term CCD (MIM \*117000) (380) was introduced later (527), and a characteristic absence of oxidative enzyme activity in the core area secondary to mitochondrial depletion was identified as the histopathologic hallmark of the condition (528).

#### 127.7.1.1 Special Features of Muscle Pathology.

Muscle biopsy demonstrates amorphous central areas in most muscle fibers. Histochemical staining shows the absence of oxidative and glycolytic enzymatic activity from these central core regions. Central cores may be single or multiple, or central or eccentric (95,528–530), but they commonly run along a significant extent of the longitudinal muscle fiber axis (531,532). Marked type 1 predominance or uniformity and hypotrophy are typical, whereas type 2 fibers may show hypertrophy, splitting or atrophy. Type 1 uniformity may be the only abnormal feature at presentation (530,533). Central cores are typically found in type 1 fibers but may occasionally also be observed in type 2 fibers; one report describes the predominance of type 2C fibers with cores in most of these fibers (534). The degree of histopathologic changes may be variable and, as with all pathological interpretation, sampling site and the age of the patient have to be taken into account. Substantial increases in fat and connective tissue but not more overtly dystrophic features such as necrotic or regenerating fibers have been described in some patients, probably reflecting a marked degree of selective involvement as demonstrated on muscle MRI (89,535).

Electron microscopy demonstrates that: (1) the cores lack mitochondria and sarcoplasmic reticulum; (2) there are variable degrees of myofibrillar disorganization; and (3) abnormal Z-band material has accumulated. The cores are usually sharply demarcated from the surrounding normal myofibrils (536). Some (“structured”) cores preserve a degree of myofibrillar organization and, therefore, retain some ATPase activity; other (“unstructured”) cores do not, and can be found in the same muscle biopsy (79,531). The sarcoplasmic reticulum and T-tubule systems are also affected, with an increase in the abundance of both organelle systems (537).

Immunohistochemical studies have demonstrated abnormal expression of various sarcomeric and intermediate filament proteins (112,538,539). Abnormal expression of slow myosin isoforms corresponding to the observed type 1 predominance on histochemical stains has been repeatedly described, but the organization of myosin and other sarcomere components is rarely disturbed (539). Abnormal distribution of desmin in and around the core areas is prominent (112,538). Central cores stain strongly positive with antibodies to the actin cross-linking protein filamin C, but this is a nonspecific finding and may be observed in other situations associated with core formation (540). More recently, distinct abnormalities of proteins involved in calcium handling and homeostasis have been suggested to differentiate between distinct specific genetic backgrounds associated with core myopathies (541).

Both the etiology and pathogenesis of central cores remain unresolved and are the topic of ongoing investigation in animal models of the condition (for a review, see Reference (542)). Core formation is not a primary pathologic process specific to CCD but can be observed in other contexts such as in several different clinical disorders (543), following tenotomy (137), secondary to denervation (“target-fibers”) (529), during reinnervation in experimental animals (544) or even in healthy probands following eccentric exercise (545). Biopsy features of CCD may be found in association with hypertrophic cardiomyopathy but, sometimes, with little or no clinical evidence of a skeletal myopathy (160,546). It is also important to emphasize that the presence of cores on muscle biopsy without associated weakness, as has been reported in some malignant hyperthermia susceptible individuals (547), is not sufficient to constitute a diagnosis of a core myopathy. Features of CCD and other congenital myopathies may be observed in the same biopsy, and the common occurrence of central cores, minicores, and nemaline bodies in the same patient has been repeatedly reported (123,154,155) and recently been attributed to a wide range of different genetic backgrounds (see Section 127.7.1.6). Therefore, care must be taken in the interpretation of a muscle biopsy with features of CCD in the presence of another disease entity or if the clinical presentation is atypical.

**127.7.1.2 Clinical Characteristics.** CCD is typically transmitted as an autosomal dominant trait and presents

in infancy with hypotonia or in early childhood with motor developmental delay (59,79,534,548–552); there is, however, marked clinical variability, and much milder (122,531,553–555) as well as more severe presentations within the range of the fetal akinesia sequence (45) have been reported, often in sporadic cases and associated with recessive inheritance. Variation in age of onset and severity may occur within the same family (536,556,557). Myalgia, muscle stiffness and exertional weakness with or without rhabdomyolysis are often associated and may be the only presenting feature (558–560). Weakness in most familial cases is pronounced in the hip girdle and axial muscle groups (79,534,548–552), and, in rare patients reported before the molecular resolution of the condition, may be associated with focal wasting (561). An adult-onset, almost exclusively axial myopathy has been recognized recently and may be a late myopathic manifestation of some MH mutations (555). Facial involvement is usually mild, and lack of complete eye closure may be the only finding. Extraocular muscle involvement is not a prominent feature in dominant CCD but is common in recessive *RYR1*-related myopathies. Bulbar involvement and associated chewing or swallowing difficulties are uncommon.

Orthopedic complications are common in CCD (562). Congenital dislocation of the hips, often resulting in persistent instability or hip contractures, is frequently associated and may be more likely when the child has been delivered through breech presentation (128,557,562,563). Scoliosis is a frequent feature and may be present from birth (553). Foot deformities include talipes equinovarus and pes planus (562). Contractures other than tendon Achilles tightness are rare, and many affected individuals have marked ligamentous laxity, occasionally associated with patellar instability (562,564).

Cardiac abnormalities other than mitral valve prolapse appear to be rare (560). An associated cardiomyopathy has not been reported in *RYR1*-related CCD but may occur in other myopathies with cores on muscle biopsy. For example, a group of patients with hypertrophic cardiomyopathy secondary to mutations in the *MYH7* gene encoding the slow/β myosin heavy chain may show central cores on muscle biopsy but typically do not have associated muscle weakness (see Section 127.9.1 and Section 127.7.1.6) (160). Respiratory involvement in typical dominantly inherited CCD is rare and has only been reported in a few isolated cases (565,566).

Malignant hyperthermia is a frequent complication (183). Many patients with CCD test positive for the malignant hyperthermia susceptibility (MHS) trait (560,567) whereas MH-susceptibility has been excluded in others. Considering that many of the more recently identified *RYR1* mutations have not yet been functionally characterized or formally assessed for their potential MH risk, our personal practice is to consider all patients with CCD at risk and to advise appropriate precautions

during general anesthesia unless proven otherwise. For the association between CCD and the potential MH risk see reference (190).

Apart from the most severe neonatal cases and some of those with congenital dislocation of the hips (45,126), most patients achieve the ability to walk independently. The course of CCD is static or only slowly progressive, even over prolonged periods of follow-up (568). Affected women may show intermittent deterioration of symptoms during or after pregnancy (192).

SCK activity is usually normal, but some patients have shown elevations up to 6–14 times normal (556,569,570).

Muscle ultrasound may be helpful in the assessment of individuals from CCD families, as it often shows a striking increase in echogenicity within the quadriceps even in paucisymptomatic individuals, with relative sparing of the rectus femoris compared with the vastus intermedius (88,571). A characteristic pattern of selective involvement on muscle MRI has been reported in patients with typical dominantly inherited CCD (89) and is distinct from that observed in core myopathies unlinked to the *RYR1* locus and from other congenital myopathies (89,535,572).

**127.7.1.3 Central Core Disease, Malignant Hyperthermia, and the King–Denborough Syndrome.** The relationship between CCD and MH is complex. Both conditions have been associated with mutations in the skeletal muscle ryanodine receptor gene (*RYR1*) but penetrance of the MH trait is low and there are likely to be additional modulators.

MH is a pharmacogenetic disorder of skeletal muscle characterized by an abnormal response to muscle relaxants such as succinylcholine and to volatile anesthetics (573). It is a severe and sometimes fatal reaction characterized by muscular rigidity, rhabdomyolysis, rapid increase in body temperature, and signs of generalized metabolic decompensation; survivors can suffer severe renal and neurologic damage (for review see references (574,575)). Males are more often affected than females at a ratio of 2:1. The estimated incidence of MH reactions lies between 1:15,000 in children and 1:50,000 in adults (576–578); however, the trait has low penetrance (576) and susceptibility may be much higher (579), as supported by studies indicating the frequency of the MHS trait as 1:2000–1:3000 in France (580) and the carrier frequency for heterozygous *RYR1* mutations in the Japanese population as 1:2000 (581).

Diagnosis of MHS is possible by applying the in vitro contracture test (IVCT), an invasive diagnostic test based on the mechanic response of muscle fibers to the triggering agents halothane and caffeine. The IVCT is interpreted according to two different protocols, the European MH group (EMHG) protocol (582) and the North American MH registry (NAMHR) (583) protocol. According to the EMHG protocol, individuals are classified as MH normal if they are not hypersensitive to either agent and as MHS if they are hypersensitive to both. In

contrast to the NAMHR protocol, individuals are classified as MH equivocal (MHE) if they are hypersensitive to either of the two agents.

MH was recognized as a familial, autosomal dominant trait by Denborough et al. (584) in Australia. Later studies of MHS families in Australia and New Zealand (585) and other countries identified two main groups, families in which MHS was clearly transmitted as an autosomal dominant trait with or without myopathic features, and sporadic or multiplex cases with negative family history and an associated combination of consistent dysmorphic findings.

In the first group of families with clear autosomal dominant inheritance, at least some individuals had evidence of a myopathy with clinical features similar to CCD; however, central cores on biopsy were absent in those patients (550) or not always typical of CCD (532). The link between MH and CCD was established in a family in which the proband had suffered an MH reaction and his aunt was found to suffer from a mild congenital myopathy characterized by central cores and type 1 atrophy on muscle biopsy; she also had an abnormal response to halothane (183). Other individuals with CCD were subsequently reported who developed MH under anesthesia or who were MHS on testing (550,560,563,569,586). Elevated SCK levels have often been found in those individuals with a myopathy or known to be MHS (550,563,585), but the predictive value of these findings for MHS, even in CCD families, is questionable (560,587).

The second group of patients described in the original Australian series (585) and subsequent reviews (588,589) were characterized by MHS, a mild myopathy, delayed motor development, and consistent dysmorphic features comprising ptosis, down-slanting palpebral fissures, neck webbing, scoliosis, pectus deformity, short stature, and cryptorchism (i.e. King–Denborough syndrome, KDS). Additional features in other families have also included vertebral fusion, eventration of the diaphragm and spinal cord tethering (590). The four cases in King and Denborough's original series were all sporadic and male, but subsequent reports have included a few women and siblings with unaffected parents and a severe phenotype with prenatal onset (591–593). A presumably recessive MH-associated phenotype with dysmorphic features identical to the KDS has been described in the Lumbee Indians of south central Carolina ("Native American myopathy, NAM") (OMIM 255995) (380), a specific ethnic group with probable consanguinity (594). Although the majority of parents of sporadic or multiplex cases with KDS and NAM were clinically normal, in other families, mild myopathic features such as ptosis, high SCK levels, MHS on IVCT (595), and increased fatigability (596) have been reported.

KDS shares many dysmorphic features with Noonan's syndrome, and the phenotypic overlap between the two conditions has been systematically evaluated (597). Despite

the striking overlap of facial features, kyphoscoliosis is less common in Noonan's syndrome and heart defects are not usually a feature of KDS. Moderate elevation of SCK and MHS, which are common in KDS, have been reported in only one patient each with apparent Noonan's syndrome (597,598). These syndromes are likely to be etiologically distinct, and assignment of the correct diagnosis in individual cases is important because of the association with MHS in KDS but not in Noonan's syndrome.

Susceptibility to MH or MH-like disorders has also been associated with a number of other muscle disorders, including carnitine palmitoyl transferase deficiency (599), hypokalemic periodic paralysis (600), and myotonia congenita (585). For a review of the relationship between MH and other neuromuscular disorders, see references (189,190).

**127.7.1.4 Genetics of Central Core Disease and Malignant Hyperthermia.** The homology of MH to the porcine stress syndrome, a naturally occurring animal model with almost identical features due to a founder mutation (601), led to the consideration of the skeletal muscle ryanodine receptor (*RYR1*) gene at human chromosome 19q13 as a likely candidate for this condition. Its function was shown to be abnormal in MH (602,603), and some families with MH showed linkage to this area (602,604–606), as did those with CCD (607–609). The identification of mutations in the *RYR1* gene, which segregate with the disease in families with MH and CCD, suggested that the two disorders could be caused by mutations in the same gene (20,610–612). An identical mutation (Arg163Cys) was found in a family with MH and in a family with CCD (612). In another family identified because the proband had CCD, several individuals were found by IVCT to be susceptible to MH but had no evidence of CCD on muscle biopsy (613). In such families, the mutation conferring susceptibility to MH may also predispose to CCD in the presence of other (probably genetic) triggering factors (612). This model of MH and CCD is supported by reports of *RYR1* mutations that are associated with MHS in most individuals but only occasionally with CCD, or with multi-minicore myopathy (547).

*RYR1* is a large gene with 106 exons (614), and it encodes a protein of 5037 amino acids, the skeletal muscle ryanodine receptor (RyR1), a  $\text{Ca}^{++}$ -release channel located in the sarcoplasmic reticulum terminal cisterna (615), playing a crucial role in EC coupling.  $\text{Ca}^{++}$ -release via the RyR1 is primarily triggered by the dihydropyridine (DHPR) receptor, which undergoes voltage-induced conformational change allowing it to directly interact with, and activate, the RyR1 (for review, see reference (616)). The predicted structure of the ryanodine receptor suggests that the  $\text{Ca}^{++}$ -release channel is located in the C-terminal part of the protein, whereas the remaining N-terminal portions face the myoplasm and constitute the visible foot structure that interacts with the DHPR receptor (617,618).

More than 100 mutations have been identified to date in the *RYR1* gene (for review, see references (619–621); also (22,581,622–629).) The majority of *RYR1* mutations associated with CCD and MHS identified to date were dominant missense mutations with only a few small deletions reported (22,581,623,624,626–633). Of note, missense mutations associated with MHS in the heterozygous state may give rise to congenital myopathies in the homozygous state (634).

The frequency of specific MH-related mutations depends on the study population, and there are indications that a few MH-causing *RYR1* mutations may account for a significant proportion of MH cases. A single mutation (Gly341Arg) accounted for 10% of MH-susceptible cases in one series (635), and the Arg-2433Gly mutation discussed earlier was present in eight probably unrelated families. Four adjacent, novel mutations were found to account for 11% of *RYR1* mutations in a collaborative European study (636). The Arg614Cys mutation is more common in German families (637), the Gly341Arg change is frequently observed in Irish/English families (636), and the Val2168Met substitution is prevalent in Swiss MH pedigrees (636,638). The Arg4861Cys substitution has been identified in three unrelated CCD families (622), but data regarding the frequency of other CCD-related mutations are currently still emerging.

The complex genotype–phenotype correlations associated with mutations in the *RYR1* gene may be partly explained by the degree of functional differentiation within this large protein. The first mutations identified predominantly gave rise to the MHS phenotype and affected two regions of the protein mainly: the cytoplasmic N-terminal domain (MHS/CCD region 1, amino acids 35–614) and the cytoplasmic central domain (MHS/CCD region 2, amino acids 2163 to 2458). Although mutations associated with a congenital myopathy phenotype have been identified in these regions (20,612,635,639), initially many families with CCD remained genetically unresolved despite typical clinical and histopathologic features. Following identification of an “unusual” *RYR1* C-terminal mutation in a large Mexican pedigree with a severe CCD phenotype (640), there has been increasing evidence that mutations affecting the C-terminal portion of the receptor molecule (MHS/CCD region 3, amino acids 4550 to 4940) are common in patients with CCD (22,23,622–624). It has now emerged that dominant *RYR1* mutations affecting the cytoplasmic N-terminal (MHS/CCD region 1, amino acids 35–614) and central (MHS/CCD region 2, amino acids 2163–2458) domains of the protein give predominantly rise to the MHS phenotype (641), whereas the CCD phenotype is closely associated with dominant *RYR1* C-terminal (MHS/CCD region 3, amino acids 4550–4940) mutations (23,622–624,640,642), with few reported families deviating from this rule (20,639,643,644). However, as some of the above studies were based on a limited screening of the *RYR1* gene, our understanding of genotype–phenotype correlations is

likely to evolve further now that sequencing of the entire *RYR1* coding sequence has become more common.

The majority of *RYR1* mutations associated with MHS or CCD described to date was dominantly inherited, but recent evidence suggests that dominant inheritance cannot always be assumed in cases with unusual features or unexpected severity when only part of the *RYR1* gene has been screened. Homozygosity or heterozygosity for *RYR1* mutations has been rarely described in association with MHS but is increasingly recognized in the context of congenital myopathy phenotypes, more commonly of the MmD rather than the CCD type (see below). The recognition of healthy (but MHS) individuals homozygous for certain *RYR1* mutations already suggested that some mutations are milder than others (645), although for some homozygotes, the sensitivity to caffeine on the IVCT may be enhanced (640). More recently, homozygosity and compound heterozygosity for *RYR1* mutations inherited from asymptomatic parents has been reported in mild cases with histopathologic features of MmD, (see below) and, less frequently, CCD (63,625), in some cases associated with a fetal akinesia syndrome with dysmorphic features and extraocular involvement (45). One affected infant in the latter series was a compound heterozygote for Arg614Cys, one of the most common MH-associated mutations previously not associated with a congenital myopathy phenotype, and a novel Gly215Glu mutation affecting the same domain of the protein. These findings are in keeping with observations that clinically silent MH mutations may give rise to a severe phenotype in the compound heterozygous or homozygous state, owing to a combined deleterious effect on the tetrameric RyR1 protein (634).

Considering the prominence of dysmorphic features and skeletal malformations associated with recessively inherited *RYR1* mutations, compound heterozygosity or homozygosity for *RYR1* mutations is also a probable mechanism in the KDS and other related syndromes. Most published cases of KDS were either sporadic or compatible with recessive inheritance, and subtle clinical or biochemical abnormalities in a parent in some of the reported families are compatible with the carrier state of a clinically not fully penetrant mutation. Indeed, Rueffert et al. (590) reported a 15-year-old boy with MH and clinical features of KDS who had inherited a novel *RYR1* mutation in exon 48 from his mother, who only had MH and central cores on muscle biopsy but no weakness, suggesting the presence of additional modifiers in the child. Another patient with KDS was found to carry a heterozygous *RYR1* missense mutation that had occurred de novo (646). A more recently published series indicates that KDS may be consistently due to compound heterozygosity for *RYR1* missense mutations, often associated with MH and running in the family, and a second *RYR1* mutation, easily missed on routine sequencing or if only partial *RYR1* screening was performed, resulting in low quantities of functional RyR1 protein (647).

The functional effects of specific *RYR1* mutations have been studied in response to the IVCT, in cultured myotubes from probands and in various homologous and heterologous expression systems. *RYR1* mutations are thought to alter excitability and calcium homeostasis within muscle cells, but the precise molecular mechanisms behind specific genotype–phenotype correlations are still emerging. Two models for mutation-induced receptor malfunction have been proposed: depletion of sarcoplasmic reticulum calcium stores with resulting increase in cytosolic calcium levels (“leaky channel” hypothesis) (648), and a specific disturbance of EC coupling (EC uncoupling hypothesis) (649). The pathogenetic consequences of individual *RYR1* mutations appear to depend on the specific effect on this structurally complex protein.

An earlier collaborative European study (636) already suggested an association between a specific mutation and the response to the IVCT; there were also some indications of a correlation between the particular *RYR1* gene mutation in a family and the severity of MH or liability to CCD (567,636,650). Further studies based on human myotubes demonstrated increased agonist sensitivity associated with *RYR1* mutations (648,651,652); however, agonist sensitivity appears to depend on the location and nature of the mutation and may even be reduced by mutations affecting certain portions of the protein (653). Studies of a mutation (I4898T) in the RyR1 C-terminal domain associated with a severe CCD phenotype demonstrated a severe reduction in agonist-induced calcium release and an increase in the resting calcium concentration (640,654); investigation of the same mutation also revealed a marked disturbance of EC coupling (655), which was also found for some of the other mutations affecting the RyR1 C-terminal domain (656). Additional studies of *RYR1* mutants expressed in myotubes of *RYR1* knockout (“dyspedic”) mice (657) indicate that MH-only mutations increase basal release channel activity insufficiently to alter net sarcoplasmic reticulum calcium content (“compensated leak”), whereas mixed MH/CCD mutations are associated with increased channel activity sufficient to deplete sarcoplasmic reticulum calcium stores, elevated intracellular calcium stores, probably mediated by decreased calcium sensitivity (658) and reduced maximum voltage-gated calcium release.

In addition to the more established tools for RyR1 functional studies, B-lymphocytes have recently emerged as a relatively easily accessible cellular system to study the pathogenesis of *RYR1* mutations in vitro (624,659–662). Expression of functional RyR1 channels in B-lymphocytes and dendritic cells leading to altered IL-6 secretion seen with some *RYR1* mutations also suggest a potential role of RyR1 in the immune system (654,663).

A number of animal models of *RYR1*-related MHS and CCD, namely the Y522S, the R163C and the I4895T knock-in mouse, have emerged over recent years, providing valuable insights into the pathophysiology of these

conditions and the evolution of associated histopathologic changes (542,664–671).

**127.7.1.5 Penetrance and Heterogeneity in Malignant Hyperthermia.** Mutations in the *RYR1* gene account for the majority of familial MH cases, with a prevalence of causative mutations indicated at 50–70% in different populations (626,628,629,632,641,644,672,673). However, a number of studies have shown discordance between the MH phenotype and the *RYR1* genotype (650,674–681); In a family with MHS, five mutation-negative individuals gave IVCT results as MHS, although they did not carry the G1021A mutation associated in seven other family members with MHS (682). Similarly, the MHS relatives of a girl with CCD showed recombination within the *RYR1* locus (613,683). Conversely, the MH-associated mutation C1840T has been found in individuals whose IVCT test results have been normal (645,675). These findings may reflect the presence of additional *RYR1* mutations in the same patient not detected if only a partial screen was performed (673), complex genomic rearrangements involving the *RYR1* gene not identifiable on routine sequencing (480), or variations in other, functionally related genes modifying the phenotype (684,685).

Limitations of the IVCT’s capacity to assign the MHS state correctly have also to be taken into account. The IVCT was designed as a clinical test to safely identify patients at risk for MH reactions, and thresholds for this testing procedure were chosen to avoid false-negative results with potentially grave clinical consequences. In both the North American and the European protocol, therefore, IVCT sensitivity is higher than specificity, but neither reaches 100%, with important implications for the study of phenotype–genotype correlations and linkage analysis. The occasionally reported discordance between *RYR1* genotype and MH phenotype (650,681) may therefore have been due to incorrect assignment of the MH-susceptibility state, resulting in obscured genetic linkage between MHS and *RYR1* and other loci (686).

Matters are complicated further by the possibility that the *RYR1*-related MH phenotype may be more common than previously thought, as suggested by the relatively high incidence of the MHS and MHE phenotypes (1% and 5%, respectively) in a low-risk European control population (687), frequent MHS in asymptomatic parents of MH probands (688), and the recent identification of MH-related *RYR1* mutations in compound heterozygotes with a congenital myopathy phenotype and unaffected parents (45). Particularly in families where only partial *RYR1* screening has been performed, two or more recombination events may therefore be explained by the presence of independent *RYR1* mutations running within a pedigree.

Although it now seems likely that *RYR1* mutations account for the majority of MH cases, it has been suggested that the MHS phenotype may reflect the compound influence of several genes rather than one major

gene defect (689). Locus heterogeneity has been indicated by variable degrees of linkage evidence for several loci and, less frequently, cosegregation of MHS with mutations in candidate genes. Because most of these loci have been implicated only in a limited number of families or certain ethnic groups, they are, however, unlikely to account for the large number of *RYR1*-recombinant families:

- Linkage to a locus on chromosome 17q has been suggested in five MH families (lod score 3.26) (690,691), but this could not subsequently be replicated in other families (692). A five-generation Canadian family with hyperkalemic periodic paralysis has been reported, in which three affected individuals have had definite episodes of MH and another four may have had milder MH-related events (693). The two conditions cosegregate with each other and with the adult skeletal muscle sodium channel (*SCN4A*) on chromosome 17q (lod score for MH < 3). A Gly1306Ala variation in the *SCN4A* gene at this locus was also found to be associated with masseter muscle rigidity, a minor MH variant, and a positive IVCT in a single family (694).
- In a single German family, there was some evidence of linkage (lod score < 3) to a marker on chromosome 7q, adjacent to *CACNL2A*, the gene for the  $\alpha$ 2-delta subunit of the 1,4-dihydropyridine-sensitive voltage-dependent calcium channel (VDCC) (695).
- In another single German family, MH linkage to chromosome 3q13.1 (MHS4) was demonstrated (lod score 3.22) (696), although the precise gene locus remains to be defined.
- In a single French family, MH showed linkage to the  $\alpha$ 1 subunit of the 1,4-dihydropyridine-sensitive VDCC on chromosome 1q, and a likely causative mutation in this gene (*CACLN1A3* or *CACNA1S*) has been recognized (697). Previously reported mutations in this gene have been implicated in hypokalemic periodic paralysis. Another mutation in this gene was identified in a North American MH pedigree (698) and an isolated Canadian patient (699) but *CACNA1S* mutations do not appear to play a significant role in other MH populations (700).
- A European collaboration has also suggested that another candidate gene for MH may be located on chromosome 5p (701), based on studies in a Belgian MH kindred.

Malignant hyperthermia susceptibility is a feature in NAM (702), a dysmorphic syndrome recently linked to 12q13.13–14.1 (703).

#### 127.7.1.6 Heterogeneity in Central Core Disease.

Although most studies have confirmed the association between CCD and mutations in *RYR1*, the penetrance of *RYR1* mutations associated with CCD is clearly incomplete. Although the classic phenotype of CCD appears tightly associated with *RYR1* mutations, there are reasons for not assuming that every case

with cores on muscle biopsy is caused by a mutation in *RYR1*:

- One family demonstrated recombination events between CCD and *RYR1*, although too little information is provided about the CCD phenotype in this family to be certain about the interpretation (704). Also, corresponding to MHS, recombinants in a family might be caused by separate *RYR1* mutations running in the same pedigree.
- Screening of the entire *RYR1* coding sequence failed to reveal a mutation in a severely affected neonate with histopathologic and clinical features of CCD (45), indicating probable genetic heterogeneity or failure to identify a more complex rearrangement by conventional sequencing techniques as demonstrated recently (480).
- Mutations in the *ACTA1* gene, previously associated with nemaline myopathy, have also been implicated in an autosomal dominant myopathy with cores (322). However, some patients in this pedigree had an associated cardiomyopathy, which is not a feature in *RYR1*-related CCD.
- Biopsy features of CCD have been found in 17 of 25 patients with hypertrophic cardiomyopathy associated with missense mutations in the slow/ $\beta$  myosin heavy chain, *MYH7* (160). Although only two of the patients in the original pedigree had muscle weakness, more recent reports suggest that *MYH7* mutations may be associated with more overt skeletal muscle myopathies, which, however, typically show more distal involvement (705) compared with *RYR1*-related CCD.
- Central cores were demonstrated in only one of identical twin boys with CCD and arthrogryposis (706); other phenocopies have been discussed earlier (see Section 127.7.1.1).
- A patient with a CCD-like presentation and muscle biopsy was found to have a specific deficiency of fructose 1,6-diphosphatase (707). Other “genocopies” may exist.
- In addition, the common occurrence of cores and other structural abnormalities such as nemaline bodies or centralized nuclei, recognized for a long time (123,154,155) has recently been attributed to mutations in the *RYR1* (22,23,157), *DNM2* (397), *KBTBD13* (14) and *NEB* (159) genes.

It remains a matter of controversy whether every patient with CCD should undergo IVCT or be assumed to be at risk of MH. Not all patients with CCD are at risk of MH (e.g. references (63) and (640)), but susceptibility should be assumed in the absence of firm evidence to the contrary. Although some authorities recommend that every individual with CCD should have an IVCT (708), it may be more appropriate to discuss the issue with affected individuals and their relatives, and to consider other approaches, such as deferring a decision until molecular genetic testing may be better able to provide

clinical guidance. For a recent review on the relation between core myopathies and the potentially associated MH risk see reference (190).

### 127.7.2 Multi-Minicore Disease

In 1971, Engel et al. (709) described two unrelated children with nonprogressive hypotonia and muscle weakness from infancy and a characteristic muscle biopsy appearance of multiple, small, well-circumscribed foci of myofibrillar degeneration with loss of histochemical staining for mitochondrial enzymes. Since the original description, at least 100 other cases with similar histopathologic features and a wide range of clinical phenotypes have been reported under the names of multicore disease, focal loss of cross-striations, minicore myopathy, myopathy with multiple minicores, or pleocore disease. The original name for this condition, “multicore” disease (MIM \*255320, 157550) (380), has now been largely replaced by the more helpful term MmD (642), reflecting the larger number and smaller size of characteristic lesions when compared with classic CCD.

**127.7.2.1 Special Features of Muscle Pathology.** Multifocal, well-circumscribed areas characterized by reduction of oxidative staining and low myofibrillar ATPase activity are the histopathologic hallmark of MmD (709,710). The cores are often not evident on routine histologic staining and may vary substantially in size; a presentation with focal loss of cross-striations in the muscle fibers has been described in some families (179,711). In contrast to central cores, minicores that affect both type 1 and type 2 fibers are typically unstructured and extend only for a short distance along the longitudinal axis of the muscle fiber (94); the latter feature distinguishes them more clearly from CCD than does their multiplicity. Predominance of hypotrophic type 1 fibers is commonly associated and may precede the appearance of more specific features (99). Distinction between CCD and MmD may be difficult in individual cases due to a shared genetic background, and in some, minicores may evolve into central cores over time (63,530).

An increase in internal nuclei and type 2 hypertrophy are commonly associated (712), whereas in some families, whorled fibers, an increase in fat and connective tissue, and more dystrophic changes have been observed (24,94), suggesting a potential overlap with the milder end of the congenital muscular dystrophy spectrum.

Minicores are evident on electron microscopy as areas of myofibrillar disruption and paucity of mitochondria, often with degeneration of the sarcomeres and swelling or proliferation of the sarcoplasmic reticulum and transverse tubules (94). Ultrastructural studies indicate different stages of minicore formation in the same biopsy, ranging from Z-line streaming with preserved myofibrillar structure to areas with complete loss of sarcomeric organization (709).

Immunohistochemical studies in minicore myopathy have been limited and suggest sarcoplasmic reticulum and desmin abnormalities corresponding to those observed in central core disease (112). As with central cores, minicores stain strongly positive with antibodies to the actin cross-linking protein filamin C (540). More recently, distinct abnormalities of proteins involved in calcium handling and homeostasis have been reported to differentiate between distinct specific genetic backgrounds in the core myopathies (541).

Minicores in muscle are found within a range of other clinical contexts (709) such as dystrophy, denervation, and inflammatory and endocrine myopathies. Minicore formation may be induced by eccentric contractions (i.e. lengthening during activity) in healthy humans (545) and has been described in association with emetine (713) or steroid administration in rats (714). Primarily metabolic conditions such as type III glycogenosis (135) or short-chain acyl-CoA dehydrogenase (SCAD) deficiency (715) may also feature minicores on muscle biopsy.

Minicores have also been reported as an additional feature in other congenital myopathies, and the association with myotubular (centronuclear) myopathy has been particularly well documented (142,143,404,716). The simultaneous occurrence of nemaline bodies and minicores has been described occasionally (123,155). More recently, minicore-like structures, with or without additional nemaline bodies, have been reported in association with dominant mutations in the *ACTA1* gene (157).

Because minicores are thus not specific for minicore disease, the diagnosis of MmD depends on the biopsy appearance within the specific clinical context of each individual case.

**127.7.2.2 Clinical Characteristics.** MmD usually presents in infancy or childhood with hypotonia or proximal weakness; prenatal onset is also well recognized (712,717). The weakness of some individuals improves with age (718–720), although the condition of others deteriorates slowly. Several individuals have been reported with onset of MmD in adult life; they have generally had a progressive weakness and some have suffered from progressive respiratory or cardiac failure (721–724). Clinical features associated with the histopathologic appearance of MmD are markedly heterogeneous depending on the genetic background and comprise at least four different subgroups.

The most instantly recognizable classic phenotype of MmD (24,712,717) has now been attributed to recessive mutations in the selenoprotein N (*SEPN1*) gene and is characterized by spinal rigidity, scoliosis, and early respiratory impairment. Patients with this form typically present in infancy, and occasionally associated are feeding difficulties with failure to thrive. Myopathic facial features are common, the voice is typically high pitched, and there may be an associated high-arched or cleft palate. Weakness is pronounced in the axial muscles, in particular the neck and trunk flexors, and proximally,

typically affecting the shoulder girdle more than the hip girdle. Failure to acquire head control is a constant early sign. There may be marked muscle wasting, mainly affecting axial groups, the shoulder girdle and the inner thigh (“bracket-like thighs”). Scoliosis, invariably present by the early teens, is usually progressive, cervico-dorsal, and associated with dorsal lordosis and lateral trunk deviation. Respiratory failure often develops after 10 years of age in the presence of severe scoliosis and can lead to secondary cardiac failure (178,712,725,726). Respiratory impairment is often out of proportion to the overall degree of weakness, and many patients on nocturnal ventilation remain independently mobile.

The other three subgroups of MmD have now all been associated with recessive *RYR1* mutations and despite some relatively distinct features there is clearly a clinical continuum, not surprising considering the shared genetic background. Extraocular muscle involvement (MmD with external ophthalmoplegia) (MIM 255320) (380) pronounced on abduction and upward gaze may be an additional feature in a subset of patients with an otherwise similar distribution of weakness and wasting (25,179,642,711,712,727). However, with the exception of the most severely affected neonatal cases (26), respiratory impairment is usually milder than in the classic form and may improve over long periods of follow-up. External ophthalmoplegia is not always observed at presentation and may evolve over time.

Another group of patients show a milder phenotype similar to CCD (moderate form of MmD with hand involvement) characterized by predominant hip girdle weakness with relative sparing of respiratory and bulbar muscles (63). A common complaint is exercise-induced myalgia. In males, cryptorchism may be an additional feature. Patients in this group may also show a pattern of selective muscle involvement on muscle imaging similar to that observed in classic CCD caused by mutations in the C-terminal end of the *RYR1* gene (63,89,625), and distinct from the selective muscle involvement described in *SEPN1*-related myopathies (728,729). In some patients, there is additional marked distal weakness and wasting, predominantly affecting the hands (63). The observation of extraocular muscle involvement evolving over time in this group suggests a clinical continuum between the latter groups rather than distinct clinical entities. Respiratory involvement is prominent in the classic form of MmD but is less pronounced, or absent, in other clinical subgroups.

A severe form with antenatal onset, generalized arthrogryposis, dysmorphic features and mild to moderate compromise of respiratory function has been described in a few patients (MIM 607552) (717,730).

A small group of patients have been reported with congenital cardiac defects (709), and mitral valve prolapse appears particularly common. Cardiac, mainly right ventricular impairment is usually secondary to marked respiratory involvement in the *SEPN1*-related

form, but a number of cases with different genetic backgrounds have shown primary cardiomyopathy in the absence of significant respiratory compromise. Cardiac involvement adversely affects the clinical course (723). Primary cardiomyopathies can be restrictive, hypertrophic, or dilated in type (722,723,731,732) and may be associated with additional accumulation of desmin in skeletal and cardiac muscle fibers (731). This indicates that the pathogenetic mechanisms may be distinct from those involved in MmD without primary cardiac involvement, as has indeed been demonstrated in some families recently (see below).

An episode of possible MH has been reported in one boy with minicore disease (733) and in an affected woman during pregnancy (194). Features of minicore myopathy have been noted in muscle biopsies from a few families with mutations in the *RYR1* gene and susceptibility to MH but no other clinical features of a congenital myopathy (547,734). As with the other congenital myopathies, the use of potentially MH-triggering agents should be avoided. For a review on the relationship between core myopathies and MH risk see reference (190).

Single cases of MmD have been reported in association with anhidrotic ectodermal dysplasia (727), type III glycogenosis (135), and SCAD (715). Although these associations are likely to be coincidental, the reported association of MmD with multiple pterygium syndrome is more likely to be of pathogenetic significance (735), considering that both conditions share the MHS trait as a potential complication (591). Chudley et al. (736) reported an adult brother and sister from a consanguineous family with MmD who also had short stature, severe mental retardation and dysmorphic features resembling those of the KDS, musculoskeletal and facial anomalies, and pituitary hypoplasia with hypogonadotrophic hypogonadism.

**127.7.2.3 Genetics of MmD.** MmD is mainly inherited as an autosomal recessive trait, as documented in several families, most with siblings of either sex affected in one generation (59,123,179,711,718,737). In addition, numerous sporadic cases have been reported, as well as one set of identical male twins (718,738–740).

Only few reports of MmD have described pedigrees compatible with autosomal dominant inheritance (123,720,723,741–743); dominant or X-linked inheritance was proposed in one family with affected male sibs (718). In some of these families, autosomal dominant inheritance was suggested because of a parental history of mild muscle weakness in childhood without any clinical signs of myopathy but with slightly abnormal muscle biopsy features (123,720,725); however, these findings may have reflected carrier status of a recessive mutation as can be observed in other congenital myopathies. When muscle biopsies from the parents of singleton patients have been studied, they have usually been normal (123,744). In other families with proposed autosomal dominant inheritance, the diagnosis was later

changed to a muscular dystrophy (745), or unusual clinical features such as electrocardiographic evidence of a cardiomyopathy suggested a distinct entity altogether.

The marked phenotypic variability of MmD is reflected in genetic heterogeneity, and recessive mutations in both the selenoprotein N (*SEPN1*) and the skeletal muscle ryanodine receptor (*RYR1*) gene have been recently identified in clinically distinct subgroups of the condition.

**127.7.2.4 MmD and the Selenoprotein N (*SEPN1*) Gene.** Investigation of the selenoprotein N (*SEPN1*) gene on chromosome 1p36 as a candidate for MmD was prompted by the considerable clinical and histopathologic overlap between the classic phenotype of MmD and congenital muscular dystrophy with rigidity of the spine (RSMD), previously attributed to *SEPN1* mutations (746). RSMD patients have a similar clinical phenotype with marked axial weakness, spinal rigidity, early scoliosis, and respiratory impairment, and histopathologic features may be rather more myopathic than dystrophic, usually with normal SCK.

*SEPN1* involvement in the classic phenotype of MmD was suggested both by linkage data and direct mutational analysis in around 50% of patients with these clinical features (24). More than 30 *SEPN1* mutations associated with a congenital myopathy phenotype have been identified to date. *SEPN1* mutations in RSMD and MmD predominantly result in a truncated protein; missense mutations are rarer and typically affect functionally important domains of the protein such as the SECIS (747) or the selenocysteine redefinition element (748). A multisystem disorder with associated myopathy has been reported associated with mutations in the gene for selenocysteine insertion sequence-binding protein 2 (SECISBP2) (749). In addition to compound heterozygosity, homozygous mutations are unexpectedly common, even in nonconsanguineous families, reflecting the presence of few founder mutations in different European populations.

Selenoprotein N, a glycoprotein localized in the endoplasmic reticulum, belongs to a family of at least 30 different proteins that mediate the effect of selenium and play a role in several metabolic pathways and various antioxidant defense systems. Selenium is essential for the normal function of many physiologic systems (750), and deficiency states have been associated with skeletal and cardiac muscle phenotypes both in animals (751) and humans (752–754).

Selenoprotein N is highly expressed from mid-gestation to immediately prenatally (755), suggesting an important part in embryogenesis. A more specific role in myogenesis is indicated by abundant expression in fetal muscle precursor cells and the observation of a specific disturbance of satellite cell function in the *sepn1*  $-/-$  knockout mouse (756). Although the precise function of selenoprotein N in muscle remains unclear, certain important aspects have been recently emerging. A role

in calcium homeostasis is suggested by a structural motif similar to those found in calcium-binding proteins (746) and the close functional and spatial relationship between selenoprotein N and RyR1 reported in normal zebrafish and the *sepn1*  $-/-$  morphant (757,758). The latter observation in conjunction with a proposed role of Selenoprotein N in redox-regulated calcium homeostasis may explain the many clinico-pathologic similarities between *RYR1*- and *SEPN1*-related core myopathies. In addition to its implications for redox-regulated calcium homeostasis, the specific involvement of selenoprotein N in antioxidant defense systems opens the prospect of *ex vivo* administration of antioxidants such as acetylcysteine as a possible therapeutic approach (759,760).

**127.7.2.5 MmD and the Skeletal Muscle Ryanodine Receptor (*RYR1*) Gene.** MmD and CCD secondary to dominant *RYR1* mutations have generally been regarded as separate entities, considering differences in core morphology, clinical phenotype, and mode of inheritance. However, recent genetic studies have implicated recessive homozygous and compound heterozygous *RYR1* mutations in clinically distinct subgroups of MmD.

The moderate form of MmD with hand involvement shares many features with CCD and linkage evidence suggested *RYR1* involvement in families with and without additional hand involvement (63,625). In two of these families, a consanguineous Algerian and a consanguineous British family, homozygous *RYR1* mutations were subsequently identified. Despite a distinct histopathologic appearance, the pattern of selective involvement on muscle MRI and CT was similar to that observed in association with heterozygous dominant *RYR1* mutations.

MmD with external ophthalmoplegia (MIM 255320) (380) in a severely affected patient, an isolated case from a consanguineous Tunisian family, was attributed to a homozygous *RYR1* mutation, introducing a cryptic splice site in intron 101 (26). Both parents were asymptomatic carriers. This mutation was the first out-of-frame mutation described in *RYR1* and resulted in a marked depletion of the normal RyR1 transcript, probably explaining the severe phenotype. *RYR1* involvement was also suggested by linkage evidence in four additional families with a similar phenotype (25), including the family previously reported by Swash and Schwartz (179).

The *RYR1* gene is also a likely candidate for the severe form of MmD with neonatal onset and arthrogryposis, considering the phenotypic overlap with the form of CCD with fetal akinesia sequence (45).

Identification of recessive *RYR1* mutations in MmD provided the molecular basis for a possible histopathologic and clinical continuum between MmD and CCD. Although the histopathologic appearance of MmD appears to be more closely associated with recessively inherited *RYR1* mutations, dominant *RYR1* mutations occasionally give rise to minicores on muscle biopsy (530) and may have accounted for a proportion of MmD pedigrees with autosomal dominant inheritance reported

in the premolecular area. Moreover, the histopathologic appearance of MmD due to recessive *RYR1* mutations may evolve into the classic picture of CCD over long periods of follow-up (63). The clinical and histopathologic spectrum associated with mutations in the *RYR1* gene is currently expanding and may account for a wider range of phenotypes than those included in the original descriptions of CCD and MmD. Recessively inherited mutations associated with MmD and related phenotypes are more widespread throughout the *RYR1* gene (25,63) and are often associated with very low presence of the functional RyR1 protein.

In contrast to the extensively characterized dominant *RYR1* mutations associated with MHS and CCD, functional effects of recessive *RYR1* mutations associated with CCD and MmD have only been characterized in few studies to date (761–764). Based on these limited studies, pathogenetic mechanisms underlying recessive *RYR1*-related myopathies appear to be more variable with loss of calcium conductance, probably mediated by marked RyR1 protein reduction, a relatively common observation.

There is currently no murine model for recessive *RYR1*-related myopathies, however, the zebrafish *relatively relaxed* mutant (765), a sporadic mutant with marked reduction of functional RyR1 protein, closely mimicks one of the probable molecular mechanisms underlying recessive core myopathies.

**127.7.2.6 Evidence for Genetic Heterogeneity in MmD.** Although a substantial proportion of MmD could be attributed to mutations in the *SEPN1* or *RYR1* gene, there is evidence for further genetic heterogeneity:

- Half of all cases with the classic phenotype of MmD are not associated with the *SEPN1* gene and may have mutations affecting a functionally related protein (24).
- Although a proportion of MmD pedigrees with autosomal dominant inheritance are likely to be due to dominant *RYR1* mutations, distinct clinical features such as a primary cardiomyopathy (723,731) suggest a different genetic background in other families with this unusual mode of transmission. Cardiac involvement secondary to respiratory impairment is common in *SEPN1*-related MmD, but primary cardiomyopathies have notably not been documented in patients with MmD owing to confirmed mutations in the *SEPN1* or *RYR1* genes. Dominantly inherited desmin myopathy (see below) may feature minicores in addition to more typical inclusions on muscle biopsy, and the marked desmin accumulation reported in some cases with MmD and a primary cardiomyopathy (731) suggest the desmin gene as a likely candidate for this subgroup. In general, although the histopathology is usually distinct, myofibrillar myopathies other than desmin myopathy may be confused with core myopathies on a more superficial histopathologic assessment. A cardiomyopathy associated with

multi-minicores on muscle biopsy has also been documented in severely affected siblings with homozygous truncating titin mutations (766). Dominant mutations in the *ACTA1* gene, previously implicated in nemaline myopathy, may feature cores with or without nemaline bodies on muscle biopsy and are associated with a hypertrophic cardiomyopathy (322).

## 127.8 CONGENITAL FIBER TYPE DISPROPORTION

Congenital fiber type (size) disproportion (CFTD) (MIM 255310) is a histopathologic diagnosis characterized by consistent smallness of type 1 fibers compared with type 2 fibers and the absence of more specific histopathologic features. CFTD has been reported in some children with the clinical picture of a congenital myopathy but also in many other neurologic conditions and is therefore not a precise diagnostic entity. Moreover, although in some patients the histopathologic appearance of CFTD persists even after prolonged follow-up (767), in others appearances may change or more specific features may evolve over time. Insofar as CFTD is indeed a diagnosis, it is one of exclusion. For a discussion of the controversy surrounding CFTD as a diagnostic entity see reference (768).

The few incidence figures that have been published are based on studies of archival biopsies and vary between 5:4000 (767) and 149:2212 (98).

### 127.8.1 Special Features of Muscle Pathology

The diagnosis of CFTD may be employed when a patient has typical clinical features of a congenital myopathy and when muscle pathology reveals predominance and selective smallness of type 1 fibers compared with type 2 fibers (see Fig. 127-2F) but no pathognomonic features of a distinct myopathy. The pathologic criteria for this diagnosis are given in Section 127.2.2 (see Reference (94) for a full discussion). The selective smallness of type 1 fibers may be accompanied by hypertrophy of type 2 fibers, and there are some cases reported with a preponderance of type 2 fibers (102).

The first report of the histology of CFTD was that of Farkas-Bargeton et al. (769), but the term CFTD was coined by Brooke, who defined the clinical presentation of 22 affected children as well as the histologic characteristics (96,770). The essentially pathologic nature of the diagnosis has been emphasized (771), and since the consistency even of this is doubtful (767), it is recommended that genetically unresolved patients with CFTD and no specific histologic features undergo a second biopsy some years after the initial one to see if more specific histopathologic features have evolved (5). In particular, Iannaccone et al. (772) reviewed the cases of 37 children with hypotonia and identified a wide range of eventual diagnoses

underlying the pathologic appearances of CFTD, including dystrophies, neuropathies, and spinal muscular atrophies, as well as myopathies. Distinct conditions in which selective smallness of type 1 fibers may be found include the other congenital myopathies (98), congenital myotonic dystrophy (773), and congenital muscular dystrophies (82). Some children have been reported where in addition to CFTD the biopsy also showed central nuclei and myofibril degeneration, suggesting a spectrum between CFTD and centronuclear myopathy (114,454,774,775). There are a number of additional reports in the literature suggesting that the biopsy features of CFTD are also found in a variety of other disorders, including metabolic diseases and other neuromuscular or neurologic conditions, including globoid cell leukodystrophy (776). Pompe's disease (glycogenosis II), other glycogen storage diseases (776), Krabbe's leukodystrophy (771,777), facioscapulohumeral dystrophy (101), hypertrophic neuropathy (778,779), spinal muscular atrophy (780), hypothyroidism (781), Lowe's syndrome (782), deletion of the short arm of chromosome 1 (1p36) (783), or fetal alcohol syndrome (776). Clarke and North (784) reviewed the literature on CFTD to this regard and emphasized that care should be taken to exclude other conditions with type 1 hypotrophy.

### 127.8.2 Clinical Characteristics

The clinical features reported in association with CFTD in the premolecular era were highly heterogeneous and are likely to reflect marked genetic heterogeneity. In the original series of Brooke and Engel, infants presented at or soon after birth with hypotonia and associated orthopedic complications were common. Facial appearance was myopathic with frequent extraocular muscle involvement and ptosis. The severity of the weakness varied considerably, but despite significant residual disability, evidence of progression was uncommon, particularly after the age of 1-years (101). Inconsistently associated features have included short stature, spinal rigidity (64,785), cerebellar hypoplasia (786–788), moderate learning difficulties (789), and seizures and aberrant skeletal maturation (790). Microstomia, campodactyly, and talipes equinovarus have been found in two patients with CFTD who were given a diagnosis of Freeman–Sheldon syndrome (791).

There have also been a number of more unusual associations, such as those of typical clinico-pathologic features of CFTD with cardiomyopathy and myofibrillar lysis inherited as an autosomal recessive trait in one family (51), and with insulin resistance in two brothers who were compound heterozygotes for mutations at the insulin receptor locus (792).

The clinical course in genetically unresolved cases with CFTD is highly variable, ranging from slow improvement (165,793) to progressive deterioration (784), the

latter often due to progressive respiratory failure requiring long-term tracheostomy (794).

The biopsy features of CFTD are also sometimes found in children or adults without a history of weakness or hypotonia in infancy, and in whom the clinical features have developed subsequently (62,795).

### 127.8.3 Genetic Background

Most cases reported in the premolecular era were sporadic but familial cases have also been described, suggestive of both autosomal-dominant (770,779,784,796–798) and autosomal-recessive inheritance (82,770,789,794,799). A number of causative genes have now been identified, some of them also implicated in other congenital myopathies such as nemaline myopathy, central core disease, multi-minicore disease and centronuclear myopathy, emphasizing the genetic and, possibly, clinico-pathologic continuum between CFTD and other congenital myopathies. Further genetic heterogeneity is expected.

Heterozygous missense mutations in the skeletal muscle  $\alpha$ -actin (*ACTA1*) gene were the first mutations identified in CFTD, in three Japanese patients with severe weakness and respiratory impairment but no extraocular muscle involvement (38).

Two sisters with CFTD, insulin resistance, severe scoliosis and respiratory muscle weakness were found to be homozygous for a G943A mutation in the selenoprotein N (*SEPN1*) gene (39), also implicated in a subgroup of MmD (24).

Heterozygous missense mutations in the  $\alpha$ -tropomyosin 3 (*TPM3*) gene, also implicated nemaline myopathy (9), were identified in five CFTD families, associated with proximal and distal weakness, respiratory impairment and ptosis but no extraocular muscle involvement (40). In a sixth family, the recurrent p.Arg168His mutation was associated with CFTD and nemaline myopathy in different family members.

Compound heterozygous mutations in the *RYR1* gene were identified in seven families with CFTD (41). Extraocular muscle involvement was a frequently associated feature and may help distinguishing distinguish *RYR1*-related CFTD from other genetic backgrounds. CFTD is also a common additional feature in *RYR1*-related congenital myopathies with central nuclei (19), suggesting a continuum between different recessively inherited *RYR1*-related myopathies.

Features of CFTD and a myosin storage myopathy were found in different members of a large dominant family harboring the same c.5807A>G mutation in the *MYH7* gene encoding the slow/ $\beta$ -cardiac myosin heavy chain (42).

Clarke et al. reported a form of CFTD compatible with X-linked inheritance in a large family with facial, bulbar and cardiorespiratory involvement and possible linkage to two loci on the long arm of the X chromosome (43).

## 127.9 MYOSIN STORAGE (HYALINE BODY) MYOPATHY

Myosin storage myopathy, previously called hyaline body myopathy (MIM 608358) (380), is clinically and probably also genetically heterogeneous. Histologically, it is characterized by subsarcolemmal accumulations of slow/ $\beta$  skeletal myosin heavy chain-positive material with a glassy (hyaline) appearance in type 1 muscle fibers. For review see reference (800).

### 127.9.1 Special Features of Muscle Pathology

The H&E and trichrome stains show subsarcolemmal or intersarcomeric accumulation of amorphous material, and often splitting of fibers, internal nuclei, fibrosis, and fatty infiltration. Fiber typing shows the affected fibers to be of type 1 (801), and in most cases, this is also the predominating fiber type. The hyaline regions are Congo red negative, devoid of oxidative enzyme activity, and rich in ATPase activity after preincubation at low pH values (802). Immunohistochemical labeling shows the regions to be occupied by slow myosin. There is no binding of antibodies against desmin (except in some at the rims of these regions), actin, tropomyosin,  $\alpha$ -B-crystallin, and several other proteins (36,802,803). Ultrastructural features include accumulation of granular, filamentous, or amorphous material without sharp demarcation toward regions of normal-looking myofibrils unconnected to the membrane (36,801–804)

### 127.9.2 Clinical Characteristics

In some of the sporadic cases and those consistent with recessive inheritance (801–803,805), onset of muscle weakness has been congenital, whereas most families with autosomal-dominant inheritance except one (806) have shown onset later in childhood or in adulthood (36,804,807). The clinical course in these families was highly variable, regardless of the age at onset. The distribution of weakness has been of limb-girdle type or scapuloperoneal. Some patients show neck flexor weakness, lumbar hyperlordosis, or calf hypertrophy. CK concentrations have been normal or slightly higher than normal, whereas electromyographic findings have been normal or myopathic (36,801–804,806). Cardiorespiratory involvement is variable but is an important cause of mortality.

### 127.9.3 Genetic Background

The first published report (801) describes an affected sib pair with healthy parents, whereas some cases have been sporadic (802,803,805) and yet another few families have shown autosomal-dominant inheritance (804,806,807). Two separate research groups were

guided by the histologic finding of accumulation of one myosin heavy chain subtype to identify the cause of this disorder, namely heterozygous missense mutations in the rod domain of the gene for slow/ $\beta$  myosin heavy chain, *MYH7* (36,808), and a genome-wide scan in a large family resulted in similar findings (37). To date, four different *MYH7* mutations have been identified in association with MSM, three of them (Leu1793Pro, Arg1845Trp and His1901Leu) associated with autosomal-dominant (36,37,809) and one (Glu1883Lys) associated with autosomal-recessive inheritance (810).

Mutations in the region of the same gene corresponding to the tail of the protein forming a coiled coil have been associated with distal myopathy type Laing (811) and other less well-defined myopathies (705). More recently, features of both CFTD and MSM have been reported in a large dominant pedigree harboring a novel heterozygous *MYH7* c.5807A>G mutation (42). In addition, *MYH7* mutations in the globular head and tail cause hypertrophic cardiomyopathy (160,812,813), occasionally associated with central cores on muscle biopsy (160).

Possible genetic heterogeneity in MSM is suggested by a family with two sibs affected by a myopathy with histologic similarity to MSM, where linkage was found to a locus on the short arm of chromosome 3 (814). However, the biopsies in this family had not been labeled with antibodies against myosin and the causative gene has not been identified yet.

## 127.10 MYOFIBRILLAR MYOPATHIES

Myofibrillar myopathy (MFM) (MIM 601419) (380) is a clinically and genetically heterogeneous disorder often occurring sporadically, with onset of muscle weakness mainly in adulthood (for review see references (815,816)). The term “myofibrillar myopathy” was introduced in the 1990s and reflects the shared pathologic features of myofibrillar dissolution with resulting accumulation of degradation products in patients with often-diverse clinical features and different genetic backgrounds. Familial cases have increasingly been reported, however, and in some of these cases, onset was in childhood. Because of the description of a few congenital cases, and in view of the structural aberrations characteristic of this disorder sometimes similar to those found in the congenital myopathies, we have included myofibrillar myopathy among the congenital muscle disorders in the current chapter.

The definition of a myofibrillar myopathy rests on the histologic findings of myofibrillar disruption and intracellular aggregation of a variety of proteins. A multitude of histologically descriptive terms, namely “desmin-storage myopathy” (817) or “desmin-related myopathy” (818) were coined because of an observed accumulation of desmin in the muscle fibers of patients (819,820), but are now used less frequently as the extended histopathologic

and genetic spectrum of these conditions is increasingly recognized (815,816,821,822).

### 127.10.1 Special Features of Muscle Pathology

The hallmark of the MFMs is disruption of myofibrils in combination with accumulation in the muscle fibers of proteins derived from the Z disk, intermediate filament or sarcolemma, or of chaperone proteins (823,824). Light microscopy shows unspecific myopathic changes such as fiber splitting and variability of fiber size, often but not invariably in combination with aggregates of granulofilamentous or amorphous congophilic material, and a variety of inclusion bodies best revealed by the trichrome method (825,826). In the regions of the aggregates, oxidative enzyme activity is low. There may be groups of small fibers, and sparse inflammatory infiltrates, but usually no necrosis or regeneration. Many of the childhood cases show predominance of type 1 fibers (827). Although histopathologic changes are nonspecific, those tend to be less pronounced with mutations in the desmin (*DES*) and  $\alpha$ B-crystalline (*CRYAB*) genes compared with other genetic backgrounds (see below). Abnormal nuclei are particularly common in *BAG3*- and *CRYAB*-related MFM.

Immunohistochemical labeling reveals an abundance of desmin (819,820), myotilin,  $\alpha$ -B-crystallin, and other muscle proteins (821,825,826,828,829). The lytic regions, in contrast, are devoid of proteins such as actin,  $\alpha$ -actinin and other sarcomeric proteins.

Electron microscopy shows disruption of the myofibrillar network, streaming of components from the Z disks, and dense structures composed of filamentous material and degrading organelles resembling hepatic Mallory bodies (820,822,826). There may be a few cytoplasmic or nemaline bodies, or autophagic vacuoles. The suggestion of distinct EM patterns associated with different genetic backgrounds has been controversial (815,830).

### 127.10.2 Clinical Characteristics

Muscle weakness is usually both proximal and distal, and symmetric and slowly progressive. Facial muscles are often spared and there is no extraocular muscle involvement. A subgroup of patients have presented with predominant involvement of respiratory muscles (32,831–833). Many patients have hypertrophic cardiomyopathy (824,826), which occasionally may be the presenting features. Some show peripheral neuropathy, including slow nerve conduction velocities. Electromyographic findings have been compatible with a myopathy in most patients but some show additional neurogenic findings and even myotonic discharges (817,826). Cataracts have been reported in some forms.

A small number of patients with congenital onset (29,32,827) have shown axial and neck flexor weakness

with hyperlordosis, scoliosis, and rigid spine. A few patients have had facial weakness. Electromyographic findings were normal or unspecifically abnormal, and SCK levels were normal or very slightly higher than normal. The remaining children in this group have had early and severe involvement of respiratory muscles. A phenotype with similar pathologic features has been reported under the name “hypertonic muscular dystrophy” in native Canadian Indians (834).

### 127.10.3 Genetic Background

A majority of patients have been sporadic cases. Although familial cases mostly show autosomal dominant inheritance (835–837), the mode of inheritance in a few families, including those in which onset has been congenital, has been autosomal recessive (27,29,32,827,834). MFM is genetically heterogeneous and mutations in genes other than those listed below are likely to be identified in future:

Mutations in the desmin (*DES*) gene were the first to be associated with MFM and have now been identified in a number of additional families (27,838–842). Onset varies from childhood to late adulthood. An associated cardiomyopathy is common and both respiratory and bulbar involvement may occur. Recessively inherited *DES* deletions have been associated with severe infantile-onset cardiomyopathy (843) or an Emery–Dreifuss muscular dystrophy-like phenotype (844).

Mutations in the  $\alpha$ -B-crystalline (*CRYAB*) gene on chromosome 11q22.3–q23.1 have been identified in a few families, associated with autosomal-dominant inheritance, late-onset, a slowly progressive course and, variably, cardiomyopathy, respiratory impairment, cataracts and peripheral nerve involvement (28,845,846). Recessive *CRYAB* mutations have been more recently identified in Canadian native Indians (30) and an isolated Caucasian case (29) with suggestive histopathologic features but an unusual clinical phenotype featuring profound truncal muscle stiffness.

Dominant mutations in the myotilin (*MYOT*) gene (31), previously reported in limb girdle muscular dystrophy LGMD1A (847,848), were described in six of 57 patients with MFM (825). *MYOT*-related MFM is associated with late-onset, frequent peripheral nerve and variable cardiac involvement.

Mutations in the *ZASP* gene encoding the Z-band alternatively spliced PDZ-motif containing protein were initially identified by Selcen and Engel (33) and subsequently in a large family with similar features previously reported by Markesbery et al. (849,850). *ZASP*-related MFM is characterized by distal weakness and variable degrees of peripheral nerve and cardiac involvement but may present with isolated high SCK.

A heterozygous Trp2710X mutation in the filamin C (*FLNC*) gene was identified in several German MFM kindreds (34), probably reflecting a founder effect, and associated with cardiorespiratory and peripheral nerve

involvement. Additional *FLNC* mutations associated with MFM were subsequently identified in different ethnic groups (851,852).

The de novo heterozygous Pro209Leu mutation in the *BAG3* gene encoding the Bcl-2 associated athanogene 3 has been identified in several sporadic cases with a particularly severe form of MFM (35,853), characterized by early-onset and a rapidly progressive course with severe cardiorespiratory involvement and an associated neuropathy.

#### 127.10.4 Pathogenetic Considerations

The pathogenesis of the MFMs has been most extensively studied for the *DES*-related forms and is currently only partially understood. Current hypotheses concerning pathogenetic mechanisms implicated in the MFMs include aborted or abnormal intermediate filament formation (854,855), disturbed interactions between desmin and its binding partners as well as downstream effects on mitochondrial positioning and function (856) or protein control mechanisms involving the ubiquitin-proteasome system and the autophagic lysosomal pathway (857). For review of molecular mechanisms in MFMs see reference (858).

#### ACKNOWLEDGMENTS

The authors thank Professors Nigel G. Laing, Susan Treves and Caroline Sewry, and Dr Kristen Nowak for constructive comments on parts of the chapter.

### Biographies

**Carina Wallgren-Pettersson** is a medical doctor specialized in Medical Genetics, working as a clinician and head of department at the Folkhälsan Department of Medical Genetics, and as a teacher and research group leader at the Department of Medical Genetics, Haartman Institute, University of Helsinki, and the Folkhälsan Institute of Genetics in Helsinki, Finland. Her research has concentrated on neuromuscular disorders, mainly on nemaline myopathy and myotubular (centronuclear) myopathy. Together with Prof Nigel G. Laing in Perth, Australia, in 1996, she initiated the forming of the International Consortium on Nemaline Myopathy. From 1993 until the beginning of the year 2000 she coordinated the research activities of another international research network, the International Consortium on Myotubular Myopathy. Carina Wallgren-Pettersson was a member the Governing Board of the EU-funded Network of Excellence Translational Research in Europe–Assessment and Treatment of Neuromuscular Diseases (TREAT-NMD), as representative for the University of Helsinki, and is now a member of the TREAT-NMD Alliance.

**Heinz Jungbluth** is a Pediatric Neurologist specialized in neuromuscular disorders, working as a clinician and head of the neuromuscular service at the Evelina Children's Hospital, St Thomas Hospital, London, and as a researcher at the Clinical Neuroscience Division, IoP, King's College, London, United Kingdom. His main research interest is in the genetics of neurological and neuromuscular disorders. His research to date has concentrated mainly on the congenital myopathies, in particular those associated with mutations in the skeletal muscle ryanodine receptor (*RYR1*) gene, one of the more common causes of inherited neuromuscular disease. He has organized and chaired several dedicated European Neuromuscular Centre (ENMC) workshops on Multi-minicore Disease, *RYR1*-related disorders (both jointly with Dr Ana Ferreiro, Paris and Prof Francesco Muntoni, London) and Centronuclear/Myotubular Myopathy (jointly with Dr Carina Wallgren-Pettersson, Helsinki, Finland, and Dr Jocelyn Laporte, Strasbourg). He is a member of the International Congenital Myopathy Standards of Care Consensus Group.

## Spinal Muscular Atrophies

*Sabine Rudnik-Schöneborn and Klaus Zerres*

Institute for Human Genetics, Medical Faculty, RWTH Aachen, Aachen, Germany

**128.1 INTRODUCTION: DEFINITION**

The term spinal muscular atrophy (SMA) comprises a clinically and genetically heterogeneous group of diseases characterized by degeneration and loss of the anterior horn cells in the spinal cord, and sometimes also in the brainstem nuclei, resulting in muscle weakness and atrophy (1). The sensory neurons are clinically spared, and there are generally no signs of upper motor neuron (pyramidal tract) involvement. With increasing identification of the underlying genetic defects, our understanding of the pathogenetic mechanisms, clinical spectrum, and possible therapeutic options has much improved in the past 20 years. Because no cure is yet available, genetic counseling and prognostic considerations are of great importance.

The subdivision of the SMAs into separate genetic and clinical entities (Table 128-1) is still controversial without distinct biochemical or molecular genetic criteria for each of the listed entities. The criteria used are age of onset, severity (progression and age of death), distribution of weakness, inclusion of additional features, and modes of inheritance. Gene defects have been identified by the end of 2010 in infantile SMA type I–III, X-linked SMA, SMA with primary respiratory distress type 1 (SMARD1), few autosomal dominant SMA types, different types of distal SMA (hereditary motor neuropathy (HMN)), and bulbospinal neuronopathy (Kennedy's syndrome).

Much semantic confusion exists in the description of the various SMAs, which is a result of the widespread use of synonyms. In this chapter, a rational approach is made to clarify the relevant types, synonyms, and eponyms under consideration of the current advances in molecular genetic research.

**128.2 PROXIMAL SPINAL MUSCULAR ATROPHY**

The proximal SMAs can be divided into autosomal recessive and autosomal dominant types. Clinically, there is no way of separating the dominant from the recessive forms. Infantile SMA is one of the most common inherited

diseases leading to death in early infancy. Because of the relative importance in neuropediatric departments and genetic counseling, the clinical features and genetics are reviewed in detail.

**128.2.1 Epidemiology**

Most cases of proximal SMA are inherited as autosomal recessive traits. Epidemiologic data of childhood-onset SMA have been summarized by Emery (2) and reviewed by Ogino and Wilson (3) and Jedrzejowska et al. (4).

Data for the most severe type I (Werdnig–Hoffmann) disease, in which affected children usually do not survive beyond the first few years, suggest that the birth incidence varies between 1:25,000 and about 1:10,000 (3). The incidence is much higher in certain inbred communities. Variants of early-onset SMA are very rare, accounting for only about 2% of infantile and childhood cases (5).

The more benign forms of the disease (type II and type III) have a prevalence among children as high as 1:25,000 and around 1:83,000 in the general population (3). Assuming an incidence of about 1:10 000 for all types of autosomal recessive SMAs, a heterozygosity frequency for purposes of genetic counseling would be 1 in 50; however, by molecular genetic carrier screening in the normal population it was found that the carrier frequency in the Caucasian population is much higher, i.e., 1 in 35 carries a heterozygous SMN1 gene deletion (4). This discrepancy is still a matter of debate and may be explained by a reduced penetrance or by atypical clinical pictures that escape diagnostic recognition.

It has been estimated that adult SMA accounts for 8% of all SMA cases, with a prevalence of 0.32 per 100,000 of the population (6).

Autosomal dominantly inherited SMA is extremely rare. According to a rough estimate, less than 2% of cases with an onset before 10 years of age show a parent-to-child transmission (7). Although vertical transmission of childhood-onset SMA is an exception, autosomal dominant transmission can be found in about two-thirds of the adult-onset proximal SMAs ((8), own series).

**TABLE 128-1 Classification of Spinal Muscular Atrophies**

1. Proximal SMA (80–90%)
  - 1.1 Autosomal recessive SMA
    - Infantile SMA (SMA I–III)
    - Adult SMA (SMA IV)
  - 1.2 Autosomal dominant SMA (juvenile and adult forms)
2. Variants of infantile SMA
  - 2.1 Diaphragmatic SMA (SMARD) (ar)
  - 2.2 SMA plus cerebellar hypoplasia (ar)
  - 2.3 SMA plus arthrogryposis and bone fractures (ar, XI)
  - 2.4 SMA plus myoclonic epilepsy (ar)
3. Nonproximal SMA
  - 3.1 Distal SMA (ad, ar, XI)
  - 3.2 Scapuloperoneal SMA (ad, ar)
4. Bulbar palsy
  - 4.1 Adult-onset bulbar palsy (ad)
  - 4.2 Progressive bulbar palsy of childhood type Fazio–Londe(ar)
  - 4.3 Bulbar palsy with deafness (Brown–Vialeto–van Laere syndrome) (mostly ar)
5. Spinobulbar muscular atrophy type, Kennedy’s disease (XI)

ar, autosomal recessive; ad, autosomal dominant; XI, X-linked.

## 128.2.2 History

In 1891, Guido Werdnig (1844–1919), an Austrian neurologist from the University of Graz, described two brothers with proximal SMA (9). Two years later (1893), Johann Hoffmann (1857–1919), a German neurologist from the University of Heidelberg, described four cases belonging to two families (10). Some of these children did not show the fatal course, which is usually meant by the term Werdnig–Hoffmann disease. The description of Oppenheim’s “myatonia congenita,” later changed to “amyotonia congenita,” led to confusion for several decades. It is believed that heterogeneous conditions have been summarized, among them many proximal SMAs. Kugelberg and Welander (11,12) described 12 patients belonging to eight sibships with an onset between 2 and 17 years. All were able to walk at least 8 to 9 years after the symptoms started.

Following the first descriptions, more than a century ago, many systematic studies about various aspects on SMA have been published. Most of the older descriptions are relevant and important even today. The first systematic monograph was published in 1951 by Sven Brandt, who collected and investigated all patients in Denmark (13). Irena Hausmanowa-Petrusewicz from Poland made essential contributions to nearly all aspects of childhood-onset SMA (14). John Pearn performed a systematic study about various aspects of childhood and adult SMA in northeastern England and, between 1977 and 1980, published numerous fundamental papers about SMA.

In 1990, the gene responsible for infantile and juvenile SMA was mapped to chromosome 5q13, and this entity was further denoted as SMA 5q. In 1995, homozygous deletions in the survival motor neuron (SMN1) gene were found by the group of Judith Melki, France, to be the leading cause of SMA 5q (15), whereas a smaller number of patients showed homozygous deletions in other genes of this highly complex region, such as the neuronal apoptosis inhibitory protein (NAIP) gene (16). The SMN1 gene proved to be the most important causative gene of SMA 5q and has further been studied on the protein level, in cell cultures, and in animal models.

With the foundation of the International SMA Consortium in 1990, supported by the European Neuromuscular Research Center and the American Muscular Dystrophy Association, diagnostic criteria have been proposed and research activities coordinated. Before understanding the genetic basis of infantile SMA, diagnostic criteria were defined in order to collect a homogeneous sample of patients for subsequent linkage studies (17). Following the SMN gene identification, the American self-support group “Families of SMA” initiated and financed international research activities with the aim to find a treatment for infantile SMA ([www.fsma.org](http://www.fsma.org)). In Europe TREAT-NMD (Translational Research in Europe for the Assessment and Treatment of Neuromuscular Diseases), a Network of Excellence funded within the sixth Framework Programme of the European Commission, was founded in 2007 ([www.treat-nmd.eu](http://www.treat-nmd.eu)). TREAT-NMD is a network for the neuromuscular field focused on the development of novel therapeutic approaches and establishing the best-practice care for neuromuscular patients worldwide. TREAT-NMD created a global registry for SMA combining standardized information from each of the national registries.

## 128.2.3 Clinical Picture

The clinical and laboratory criteria of proximal SMA were repeatedly defined by the International SMA Consortium (Table 128-2) (17,18). Meanwhile genetic screening of the SMN1 gene has become an important diagnostic tool and has generally replaced invasive procedures in SMA 5q. In other SMA forms, where the genetic basis is heterogeneous or largely unknown, clinical work-up still needs to be done in experienced hands.

As far as the clinical investigations are concerned, biochemical investigations of serum or cerebrospinal fluid show no specific abnormality. Muscle enzyme (creatine kinase (CK)) activity is normal or only slightly increased mostly in juvenile-onset cases (19). If the serum CK level is more than fivefold above the upper limit of normal, a myopathy is more likely.

Electromyographically, neurogenic changes can be seen with abnormal spontaneous activity (fibrillations, positive sharp waves, fasciculations) in progressive disease courses. Motor unit potentials elicited by

**TABLE 128-2** Diagnostic Criteria of Proximal Spinal Muscular Atrophy (18)

Inclusion Criteria	Exclusion Criteria
Symmetric muscle weakness of trunk and limbs	Involvement of extraocular muscles, diaphragm and myocardium*
Proximal muscles > distal	Marked facial weakness*
Lower limbs > upper limbs	CNS dysfunction
Fasciculations of tongue, tremor of hands CK usually <5 times the upper normal limit	Arthrogryposis (but rarely seen in severe SMA type I)
Neurogenic changes in EMG and muscle biopsy	
Homozygous absence/mutation of the SMN1 gene	Reduction of motor nerve conduction velocities <70% of lower normal limit or abnormal sensory nerve action potentials in SMA II–III (motor and sensory conduction can be markedly abnormal in SMA I)

CK, creatine kinase; CNS, central nervous system; EMG, electromyography; SMA, spinal muscular atrophy; SMN, survival motor neuron.

\*Exceptions are rare congenital onset cases with external ophthalmoplegia and facial weakness.

voluntary effort have an increased mean duration and amplitude, indicating reinnervation. The interference pattern on increasing effort is reduced because of loss of motor units.

Peripheral nerve conduction is generally normal. However, in severe cases of SMA type I, motor and sensory conduction velocities can be reduced owing to depletion of fast-conducting large-diameter nerve fibers.

Muscle biopsy specimens typically show large group atrophy in severe SMA (Figure 128-1), whereas the atrophic groups of both fiber types appear to be smaller in the chronic forms. Histochemical staining reveals fiber type grouping mainly in the more chronic cases reflecting reinnervation. In SMA I and II, hypertrophic fibers of type I are distributed among the atrophic fibers of either histochemical type. In SMA III and IV, there is prominent reinnervation with type grouping, but small angular fibers occurring in small groups or singly are also present and signal ongoing denervation.

In accordance with the diagnostic criteria, peripheral nerves are morphologically normal in the vast majority of SMA patients. When axonal degeneration is observed in motor nerves, it has been attributed to a dying-forward phenomenon as a consequence of motor neuron degeneration, but recent studies suggest a primary axonal dysfunction in SMA 5q. Corresponding to the electroneurographic findings, there can be significant axonal degeneration not only in motor but also in sensory nerves at least in SMA I (20).

**FIGURE 128-1** Muscle biopsy findings in severe (A) and mild (B) SMA. Note large group atrophy and type I fiber hypertrophy in severe SMA, whereas small group atrophies and fiber type grouping predominate in mild SMA (ATPase staining).

In the spinal cord (Figure 128-2), pathologic features are gliosis of anterior horns without areas of demyelination. Although the posterior roots appear to be normal, distinct demyelination can be seen in the anterior roots. The degenerated anterior horn cells become small and pycnotic until they completely disappear. Because in patients with severe SMA other parts of the central nervous system (CNS) also show degenerative processes (21), the full spectrum of pathologic abnormalities in SMA is yet to be clarified.

**128.2.3.1 Clinical Course and Classification.** The clinical picture of proximal SMA is highly variable, indicating a continuous spectrum with ages of onset from before birth to adulthood rather than to distinct disease subgroups. The currently used classification schemes take age of onset, life span, and motor development into account but vary to a large extent, so that it is difficult to compare the defined subgroups with each other. This problem was addressed by Dubowitz (22) and Russman (23) and resulted in the proposal of a common classification by the International SMA Consortium. The subgrouping of childhood-onset SMA was basically suggested as a guideline for inclusion of patients in DNA studies and later analysis of genotype–phenotype correlations after identification of the gene for autosomal recessive childhood SMA. A major problem with the existing classifications is that the prognosis often turns out to be better than that associated with a defined subtype. This means that a patient initially classified as severe type I SMA may have to be reassigned to intermediate type II or even type III when the patient's life span exceeds the predicted age of death. Therefore, it is better to define SMA types I–IV by achieved motor functions and by age of onset rather than by prognostic limitations (Table 128-3).

**128.2.3.2 SMA Type I.** The clinical signs of the most severe SMA type, which is also called Werdnig–Hoffmann disease, are evident at birth or soon thereafter, with a median age of onset of 1 month (24). Nearly all patients present by 6 months of age, and one-third have decreased fetal movements.

Symptoms are profound hypotonia and generalized weakness (Figure 128-3). The infants do not kick well and are never able to sit unaided. Weakness is proximally

**TABLE 128-3 Classification of Proximal Spinal Muscular Atrophy**

SMA Type	Principal Synonyms	Definition	Genetics
I	Werdnig–Hoffmann disease Acute infantile SMA	Sitting not achieved Onset usually within the first 6 months Death >90% by 10 years	Autosomal recessive
II	Chronic childhood SMA  Arrested Werdnig–Hoffmann disease	Unaided sitting possible, walking not achieved Onset usually in the first year of life Survival >90% by 10 years	Autosomal recessive
III	Kugelberg–Wielander disease Juvenile SMA	Walking without aids achieved – IIIa: Onset ≤ 3 years – IIIb: Onset >3 years Mild course, life span not markedly reduced	Autosomal recessive Excess of men
IV	Adult SMA	Onset >30 years Variable severity, normal life span	Mostly sporadic Autosomal dominant Autosomal recessive (extremely rare)

SMA, spinal muscular atrophy.

**FIGURE 128-2** Cross-section of gray matter in spinal cord of an infant who died from severe SMA. Motor neurons are grossly reduced in number, and surviving cells are pycnotic (arrows). (Courtesy of Professor John Pearn, Herston Qld, Australia.)

pronounced, and the legs are weaker than the arms. Tendon reflexes are absent. Tongue fasciculations and hand tremor are characteristic features of infantile SMA, whereas muscle wasting is often inconspicuous. The diaphragm and the extraocular muscles tend to be spared, which distinguishes classic SMA from the rare diaphragmatic SMA variant. A certain percentage of infants show mild joint limitations from birth (limited hip abduction or knee and elbow extension and ulnar deviation of the hands), but this is much less severe than in infants with arthrogryposis multiplex congenita. Typical ulnar deviation in the hands is shown in [Figure 128-4](#). Weakness affects both bulbar and respiratory muscles with a rapid progression in most cases; the median age at death of patients with diagnosis in the first 6 months was 6–7 months (25). Chronic forms exist ([Figure 128-5](#)), and some patients survive into adulthood (26). Because an increasing number of countries are offering mechanical respiratory support either through tracheostomy or noninvasive ventilation, the survival probabilities have changed dramatically (27–29). Although the question

**FIGURE 128-3** Girl with SMA type I at the age of 10 months, a few weeks before her death.

of quality of life is still a matter of debate in the totally paralyzed and ventilated SMA type I children, survival into the thirties has rarely been reported on a stable functional level. Moreover, there is concern about previously unknown complications from the cardiovascular side in long-term SMA type I, including bradycardia progression to a cardiac standstill (30) and other features suggesting autonomic nervous system defects.

**128.2.3.3 SMA Type II.** The clinical course of SMA type II or chronic childhood SMA, arrested Werdnig–Hoffmann disease, or intermediate-type SMA is marked by periods of apparent arrest in the clinical progression. The age of onset and presenting signs may be indistinguishable from SMA type I, although the median age of onset is generally later (8 months). The children fail to pass motor milestones because of proximal weakness and hypotonia within the first 18 months of life. There is a wide variability of clinical severity, ranging from children who have early difficulty sitting ([Figure 128-6](#)) or rolling over to patients who can crawl or walk with support. For practical purposes, this group is defined by the ability to sit independently, because the children never learn to stand or walk unaided. Pronounced weakness of trunk muscles in the nonambulatory patients results

**FIGURE 128-4** Ulnar deviation in the hands of a 2-month-old paralyzed infant with severe SMA type. (Courtesy of Professor John Pearn, Herston Qld, Australia, by kind permission of Dr John Wilson, The Hospital for Sick Children, London.)

in spine deformities and reduces lung capacity. Contractures develop early in all major joints owing to synergist-antagonist imbalance (Figure 128-7). Hand tremor and fasciculations are characteristic features. Most patients survive into adulthood (Table 128-3), and life span can be influenced by unrelated factors, such as body weight, growth spurts, and infections.

Because progression is slow and survival into adulthood is the rule rather than the exception, major emphasis must be placed on schooling and education. It is important to know that the cognitive functions are not affected in SMA. Children with chronic SMA often seem to be brighter than others of the same age, which may be related to early speech development. In a large German study, general intelligence measured in 96 SMA patients, who had mostly type II SMA, was not different from that of age-matched controls and their healthy sibs (31).

**128.2.3.4 SMA Type III.** A mild form of childhood and juvenile SMA type III is known as Kugelberg-Welander disease and shows a wide range of clinical onset from the first year of life until the third decade. Patients with SMA type III learn to walk without support, which distinguishes them from those with SMA type II. For prognostic reasons, this group has been separated into types IIIa and IIIb (Table 128-3).

In SMA type IIIa, onset is in the first 3 years of life, the children have early walking difficulties and often fail to pass further motor milestones, for example, rising from the floor or climbing steps (Figure 128-8). Because many patients are nonambulatory by school age, they are much more handicapped than those whose walking difficulties begin in youth or adulthood. In a German and Polish study, 50% of SMA type IIIa patients were confined to a wheelchair 14 years after onset (32). Similar results were obtained in a study undertaken in Hong Kong, where 50% of patients were chair-bound 20 years after onset (28). In SMA type IIIb, the first signs of weakness occur between 3 and 30 years and are mainly problems in running, climbing, and sports. As in SMA II, tremor of the outstretched hands and limb

**FIGURE 128-5** SMA type I patient with prolonged survival. Current age 7 years, deformed thorax; death at 9 years after numerous lung infections.

fasciculations are frequent findings. The progression can be very slow or even imperceptible. About 50% of SMA type IIIb patients are still ambulatory after having had the disease for 45 years (28,32). Depending on the degree of weakness, spine deformities and contractures are frequent complications, mainly in the chair-bound patients. Respiratory insufficiency requiring assisted ventilation can become a problem in older, immobile patients late in the disease; however, life expectancy is not much reduced.

**128.2.3.5 SMA Type IV.** Although there is a spectrum of manifestations in SMA types I–III, with overlapping features between the subgroups, SMA type IV or adult SMA is a more distinct and heterogeneous entity. Lower motor neuron disease is also seen in series of patients with motor neuron disease including amyotrophic lateral sclerosis (ALS), i.e., a distinction is not always possible and variable phenotypes can occur within a family. Attempts were made to classify subtypes of adult-onset SMA according to the distribution for weakness and progression (33,34). Because the underlying pathogenetic mechanisms of the different types remain to be identified, subgrouping and prediction of disease courses is difficult at least at the time of diagnosis.

Only exceptionally, SMA 5q starts after 30 years of age. These patients have a strictly proximal involvement, with marked weakness of the pelvic girdle muscles, particularly of the iliopsoas muscle. It is believed that these patients have a mild SMA 5q owing to a large number

**FIGURE 128-6** Twin brothers with early-onset SMA type II. A sitting position is maintained only for several minutes followed by a “pocket knife” phenomenon.

of SMN2 gene copies, but clinical variability cannot be explained by the SMN genes alone. Some patients have an age of onset between 20 and 32, and can thus be classified borderline between SMA III and IV. In our study, onset in adult SMA ranged from 30 to 60 years, with pronounced proximal weakness, particularly of the limb girdle and thigh muscles. The condition is relatively benign with slow clinical progression, and a normal life span can be expected (34,35). It must be stressed that in contrast to SMA I–III, recurrence of SMA IV within a sibship is exceptional. Since there is a marked predominance of males, hormonal or modifying genetic factors are assumed to influence the pathophysiology (34).

### 128.2.4 Genetics

The proximal SMAs are genetically heterogeneous; both autosomal recessive and autosomal dominant genes are known to cause childhood- or adult-onset SMA. The clinical picture does not allow the distinction of different modes of inheritance, thus leading to problems of genetic counseling in families in which only one subject is affected and in whom no gene defect is detected.

Except for Kennedy syndrome and the distinct entity of infantile SMA with congenital contractures and bone fractures (see section on Variants of Childhood Onset), there is no convincing evidence of an X-linked proximal SMA. There is an excess of male patients, however, best noted among the simplex families and in the milder forms of proximal SMA.

**128.2.4.1 Autosomal Dominant SMA.** As stated earlier, autosomal dominant proximal SMA is extremely rare, but was observed more frequently in late onset SMA IV than autosomal recessive inheritance in some European studies. The course is usually mild or only slowly progressive, and most patients remain ambulatory many years after onset.

Pearn (8) suggested that there are two dominant genes, one accounting for the childhood-onset form and one for the adult-onset form. Penetrance was thought to be nearly complete in both forms. There is marked intrafamilial variability of age of onset and

**FIGURE 128-7** Proximal childhood-onset SMA. An 11-year-old girl showing gross kyphoscoliosis. (Courtesy of Professor John Pearn, Herston Qld, Australia.)

**FIGURE 128-8** SMA type III in a 3-year-old boy. Rising with Gower's sign, proximal muscle wasting.

progression, which is not compatible with the subdivision into two clinically defined genetic entities (36). Pedigree analysis and molecular testing can be helpful to identify pseudodominant families in which one parent is homozygous and the other heterozygous for an autosomal recessive gene.

Large dominant pedigrees of late-onset SMA were reported from Brazil and designated SMA type Finkel (OMIM 182980) (37,38). Mean age of onset was 48 years; muscle cramps and respiratory insufficiency occurred early in the disease course. The gene defect has been recently identified on chromosome 20q13.3 (VABP gene) and gave evidence of a founder effect from a common Portuguese ancestor in these and other families (39). Mutations in the VABP gene were also detected in atypical and typical ALS families with marked interfamilial and intrafamilial variability, and some families showed overlapping features of SMA and ALS (39). In other populations, VABP gene mutations seem to be an exception (40).

**FIGURE 128-9** Multiplex ligation-dependent probe amplification (MLPA): detection of a homozygous (A) or heterozygous (B) SMN1 gene deletion.

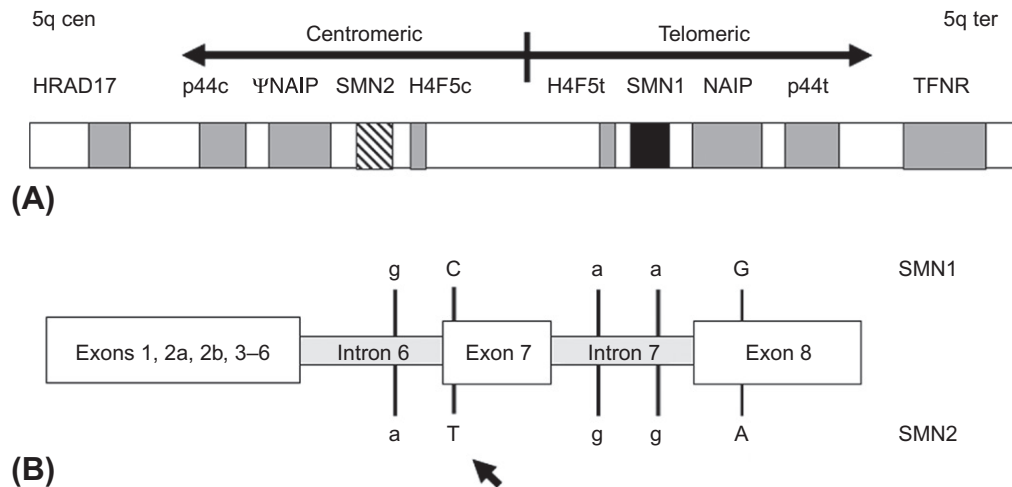

A further locus for an early-onset proximal SMA was demonstrated on 14q32 in a large North American family (41), but still many genetic defects and chromosomal loci are so far unknown in autosomal dominant SMA.

**128.2.4.2 Autosomal Recessive SMA.** The majority of cases with SMA are autosomal recessively inherited. Taking the acute and chronic forms of childhood SMA together, the incidence is at least 1:10,000 among whites.

**128.2.4.3 Molecular Biology.** The recessive gene responsible for most families with childhood SMA has been localized in 1990 to a small region of the long arm of chromosome 5 (5q11.2-q13.3). Different genes and microsatellite markers were identified in the 5q region that can be deleted in SMA patients. Deletions or mutations of the telomeric copy of survival motor neuron (SMN1) gene are disease specific and confirm the diagnosis (15). The SMN1 gene consists of eight exons spanning about

20 kb genomic region. It encodes a 38 kDa protein with 294 amino acids, the SMN protein. Homozygous deletions of the SMN1 gene are detected in more than 90% of SMA type I–III patients and only exceptionally in SMA IV. Homozygous deletions can be made visible by single-strand conformational analysis (SSCA) or by restriction digest of polymerase chain reaction (PCR) products (42). In the vast majority of patients, exons 7 and 8 are absent, followed by a 5–10% deletion rate of exon 7 only. Moreover, isolated deletion of exon 8 has been detected in rare instances of mild SMA (43). Quantitative methods allow a direct estimation of the number of SMN1 and SMN2 gene copies, e.g., by multiplex ligation-dependent probe amplification (MLPA) (Figure 128-9).

The centromeric copy of the SMN gene (SMN2) is nearly identical with the SMN1 gene except for five

**FIGURE 128-10** Schematic representation of the two SMA genes in the chromosomal region (5q13) (A), localization of the nucleotides by which SMN1 can be distinguished from SMN2 (B). The arrow indicates the C>T base exchange in exon 7 of SMN2 that causes alternative splicing.

nucleotide differences in exon 7 and 8 (Figure 128-10), yet their transcriptional products are not the same. Although SMN1 produces full-length transcripts, SMN2 primarily gives rise to truncated transcripts lacking exon 7 (60%), exon 5 or both. The protein product SMN $\Delta$ 7 is nonfunctional and is degraded rapidly. Only minor amounts of full-length SMN transcripts (10–20%) are produced by SMN2, but this has been in the focus of therapeutic research in the past 10 years (see section on Management). The critical difference between SMN1 and SMN2 is a C>T base change in exon 7 that was believed to disrupt a putative exonic splice enhancer (ESE) and cause alternative splicing of SMN2 exon 7 (44,45). In the past years it was shown that SMN splicing machinery is much more complex and includes positively and negatively acting regulatory elements (46). Homozygous deletions of SMN2 gene can be detected in about 5% of the normal population but are not associated with a disease phenotype if at least one SMN1 copy is retained.

Only in a small number of patients (approximately 3–4%), subtle mutations in the SMN1 gene have been identified (47,48) that mostly occur as compound heterozygotes in conjunction with a deletion. Compound heterozygotes can be detected after PCR-based densitometric assessment of SMN-gene copy number, by pulsed field gel electrophoresis or by fluorescence-based carrier testing, but in the past years quantitative analysis of SMN1 and SMN2 copy numbers largely replaced these laborious methods. In routine analysis, technology based on real-time fluorescence PCR using a LightCycler (49) and TaqMan technology (50), and increasingly MLPA are in use. These quantitative methods identify patients and relatives who retain only one copy of SMN1. The information obtained in this way can be used for further diagnostic work-up of patients for genetic risk calculation in affected families (see section on Genetic Counseling).

The SMN protein is expressed in all somatic tissues and is highly conserved from yeast to man. It is involved

in RNA processing and is localized in structures called “gems” in the nucleus. The SMN protein acts in concert with several other proteins in the regeneration of the small nuclear ribonucleoproteins (snRNPs), acting as an assemblyosome in the formation of diverse RNP particles (for a review see References (46,51)). It is still unclear why SMN protein deficiency results in selective motor neuron loss, because the gene is ubiquitously expressed. More recent studies of cell cultures and animal models have shown that the SMN protein is important for axonal growth and transport of motor neurons. Additional functions are ascribed to the skeletal muscle and to the integrity of the neuromuscular junction.

**128.2.4.4 Animal Models.** The SMN protein is transcribed by the two SMN genes that were generated by a duplication on chromosome 5q around a million years ago (52); therefore, no natural animal model for infantile SMA exists. Before the SMN gene was discovered, it was hoped to find a human homolog derived from the different mouse models of motor neuron degeneration (for a review see Reference (53)). This approach was eventually successful in identifying the human homolog of the nmd mouse (54), which turned out to be the IGHMBP2 gene responsible for the SMA variant with diaphragmatic palsy (SMARD1).

Several groups have attempted to model SMA in zebrafish, *Drosophila*, and *Caenorhabditis elegans* but it was difficult to reconcile conclusions generated in different species (for a review see Reference (53)). New and emerging insights were obtained from model mice. As regards murine *smn* and *naip* genes, the number of *naip* genes is increased, but there is only one *smn* copy. Replacement of murine *smn* by human SMN2 genes resulted in transgenic mice that show features of the human disease (55–57). These mice not only produced different SMN2 numbers and had varying phenotypes resembling human SMA but also had additional features like necroses of the tail, ear and digits (58). Moreover, it was shown that

there are early abnormalities of the neuromuscular junction while motor neuron loss was recorded later in the disease course of severely affected mice (59). Splice correction by antisense oligonucleotide (ASO) therapy into the CNS increased SMN protein levels and also corrected the tail and ear necroses, which therefore appeared to be related to an innervation deficit (60).

In the transgenic mouse model created by the French investigators, exon 7 of the murine *smn* gene was removed from both mouse chromosomes in a tissue specific manner by using the Cre/loxP recombination system. Although mice with SMN deficiency restricted to the spinal cord (neuronal mutant) developed an SMA-like phenotype (61), different disease phenotypes were induced in mice in which *smn* genes were deleted in the muscle (62) or in the liver (63). These data suggest a ubiquitous role of full-length SMN protein in various mammalian cell types. It appears that the residual amount of SMN protein produced by the SMN2 genes in humans allows a normal function of other organs except motor neurons.

Eventually, treatment studies of transgenic mice have supplied first proof of concept of the feasibility of modulating the SMN2 gene for therapeutic purposes.

**128.2.4.5 Genotype–Phenotype Studies.** The proportion of clinically typical SMA patients who do not show a homozygous SMN1 deletion does not exceed 5% in SMA type I and II, but increases to 10–20% in mild SMA type III (64). Although deletions of variable size occur in SMA I, in the milder SMA II and III, gene conversion of SMN1 to SMN2 is responsible for the reduced transcription of the SMN protein. Several studies have demonstrated chimeric SMN genes with SMN2 exon 7 fused to SMN1 exon 8, which increases the number of SMN2 copies to 3–4 in milder SMA types. Thus, SMA I is caused by physical deletions of SMN1, whereas the mutations in type II and III SMA consist of replacement of SMN1 by SMN2. The number of SMN2 copies correlates with SMA subtype, age of onset, and length of survival, that is, the clinical phenotype depends primarily on the level of functional SMN protein (25,49,65). However, it is not possible to predict the course of the disease in individual patients from the size of the observed deletion or the gene conversion event, because there is a wide overlap of molecular genetic findings in the different types of SMA.

**128.2.4.6 Abnormal Phenotypes Associated with SMN Gene Deletions.** Based on molecular genetic findings, the clinical spectrum of SMA 5q was extended to more severe and atypical presentations as well as to subclinical manifestations. It is now clear that a “congenital” type of infantile SMA exists, which includes severe neonatal onset with respiratory insufficiency (66) and congenital contractures (25,67,68) (Figure 128-11). In some of these patients, a severe SMN protein deficiency was seen by the presence of homozygous SMN1 gene deletions and only one SMN2 gene copy (25). Life span is short, with death occurring soon after birth

**FIGURE 128-11** Patient with congenital SMA presenting with arthrogryposis multiplex and respiratory distress from birth, fetal arrhythmia and polyhydramnios in pregnancy. Picture taken at age 10 days, death after 18 days. Molecular genetic analysis showed a homozygous SMN1 deletion and only one SMN2 gene copy (patient 3 from (25)).

**FIGURE 128-12** Sural nerve biopsy in a patient with severe SMA type I featuring signs of congenital hypomyelination. Severe axonal loss points toward primary involvement of the sensory nervous system (patient 2 from Reference (69)).

unless under mechanical ventilation. Rarely external ophthalmoplegia, and severe peripheral (sensory and motor) nerve involvement (Figure 128-12), clinically indistinguishable from congenital hypomyelination neuropathy, can be a consequence of severe SMN deficiency (69). In this context it has to be clarified whether the rarely observed vascular perfusion abnormalities resulting in digital necroses (70,71) are a consequence of an innervation deficit or of an independent mechanism in the blood vessels.

More recently it turned out that congenital heart disease is also a feature of severe SMA associated with a small number of SMN2 copies. In our series of patients with one SMN2 copy, three out of four had a congenital heart defect, mostly atrioventricular septal defects

(72). Following this observation in humans, recent studies of transgenic mouse models confirmed early-stage developmental defects of the heart, i.e., interventricular septum and left ventricular wall remodeling along with interstitial fibrosis and thinning of arterial walls (73). Other mouse models developed severe bradyarrhythmia and dilated cardiomyopathy (74,75). These studies shed a new light on SMN function in other tissues.

**128.2.4.7 Modifying Factors.** The presence of modifying factors had been studied soon after the discovery of the SMN1 gene, following the observation of families, primarily published as unlinked to chromosome 5q markers, in whom SMN1 gene deletions were found, not only in the patients but also in their unaffected sibs (Figure 128-13) (64,76–78).

Preliminary data indicate that a small fraction of patients with mild SMA have haploidentical sibs who also show deletions in the SMN1 gene, thus confirming the responsible gene locus on chromosome 5. This finding suggests that there are environmental or genetic mechanisms that can suppress the effect of

a nonfunctioning SMN1 gene and therefore reduces penetrance of the disease. The most important modifier is the SMN2 gene itself because a large number of SMN2 copies can suppress disease manifestation, but this has not explained the nonaffected relatives with homozygous SMN1 deletions. In addition, a positive modifier of SMN expression from the retained SMN2 genes is the c.859G>C variant in SMN2 first described by Prior et al. (79). A larger Spanish study showed that this variant is present in about 1–2% of the normal population but was detected in about half of the patients with two SMN2 copies and an SMA type II or III phenotype (80). The group of Wirth identified mutations in the X-linked plastin gene as an explanation for a reduced expression and a milder phenotype in females (81). Moreover, it was shown that ciliary neurotrophic factor (CNTF) deficiency results in a deterioration of SMA in a transgenic mouse model (82); comparable data in humans are not available as of February 2011.

**128.2.4.8 Sex Influence.** The question of a possible influence of gender has been a matter of controversial discussion. There was a predominance of men in the whole German study group (243:202), which was most pronounced in the mild form (type III) (82:52) (35). Only a small number of girls developed the disease after puberty. Very similar results have been obtained by Hausmanowa-Petrusewicz (83). It still needs to be clarified whether a “female-sparing factor” is responsible for a remarkable decrease in the number of affected girls in the late-onset group. Among children belonging to sibships with at least two affected siblings, no significant sex difference could be obtained in our data of 101 affected sibs out of 48 families (84).

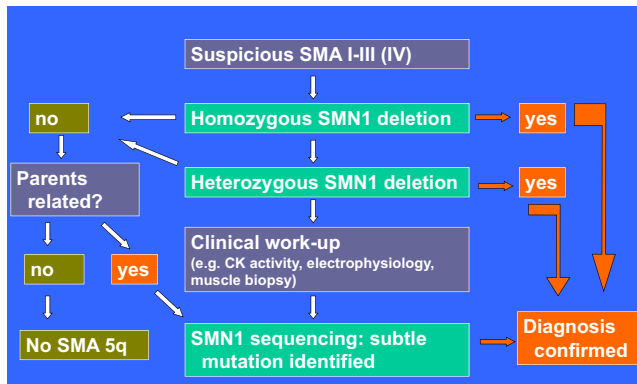

**128.2.4.9 Genetic Counseling.** Most cases of proximal SMA follow an autosomal recessive mode of inheritance. For genetic counseling, the estimated heterozygosity frequency for SMA 5q is about 1 in 50 in the Caucasian population (see section on **Epidemiology**).

The detection of homozygous deletions in the SMA region confirms the diagnosis and establishes autosomal recessive inheritance in SMA types I–III. Patients with adult-onset SMA (onset >30 years) are only exceptionally associated with alterations of the SMN1 gene. In clinically typical patients, a heterozygous SMN1 gene deletion is likely to act with a subtle mutation on the other chromosome (3–4% of patients), while in consanguineous families a homozygous subtle mutation has to be taken into account. Linkage analysis with genetic markers of the SMN region on 5q13 may point toward homozygosity and the correct diagnosis. The diagnostic algorithm for SMA 5q (Figure 128-14) has to consider the clinical picture and pedigree information. Mutation analysis of the SMN1 gene is hampered by the complex genomic region and not offered on a routine basis. It is established by cDNA analysis following RNA isolation (85) or by a long-range PCR method (86). The

**FIGURE 128-13** Family with homozygous deletions of SMN1 not only in the affected son with classical SMA type II but also in the healthy mother.

**FIGURE 128-14** Diagnostic algorithm of SMA 5q.

genetic basis of patients who are unlinked to chromosome 5q remains to be identified; in those patients other diagnoses have to be ruled out by thorough clinical examination.

Carrier testing of relatives or spouses is meanwhile an integral part of genetic counseling and has improved in sensitivity and specificity in the past years. The consequences for genetic risk calculation have been outlined in detail (3). The SMN1 copy number can be measured by quantitative methods and can reliably identify heterozygous carriers of SMN1 gene deletions. The test sensitivity does not exceed 95%, because two or more SMN1 copies are present on normal chromosomes in 3–4% of carriers. In addition, new SMN1 deletions occur in about 1% of SMA chromosomes, and subtle mutations cannot be identified by the quantitative test. Therefore, it is recommended to investigate the spouse, if the person at risk carries an SMN1 deletion or cannot be excluded as a gene carrier from previous investigations in the family.

In families in which the index patient had died before molecular studies were undertaken, the evidence of a heterozygous SMN1 gene deletion in the parents gives a clue toward the genetic defect and allows a correct risk estimation of further relatives.

Prenatal testing can be safely performed in families with proven homozygous SMN1 deletions/mutations. If there is only a heterozygous SMN1 deletion in the patient and the second mutation is unknown, prenatal diagnosis can be offered through analysis with chromosome 5q markers. A typical clinical picture in the patient is a prerequisite. Prenatal testing is not applicable in families without evidence of alterations in the SMA region on chromosome 5q.

If a spouse of a proven gene carrier has normal SMN values, this reduces the remaining risk to the offspring to a level where prenatal testing is no longer recommended. However, the detection rate through SMN1 gene deletion screening in fetal DNA has a higher sensitivity than the risk calculation based on carrier testing in the parents. If prenatal diagnosis is undertaken for unrelated reasons in a pregnancy at risk, SMN1 gene deletion screening can further reduce the fetal risk. Considering

the implications of carrier testing, it is mandatory to offer molecular genetic studies only within the context of genetic counseling.

### 128.2.5 Pregnancy

Women affected with childhood-onset SMA are unlikely to have their own children, but increasing reports of successful pregnancies even in severely handicapped SMA type II patients are encouraging. In long-standing diseases with stable lung function, the risk of major complications or deterioration seems to be small. In chair-bound patients, the preferred mode of delivery is elective caesarean section, which can be safely conducted under subarachnoid block (87). In SMA II the respiratory situation is essential for pregnancy planning. While successful pregnancies have been reported in women with vital capacities as low as 11% (88), the risk for miscarriages or stillbirths depending on the lung function is increased but yet ill-defined. In SMA II and SMA III there is an increased preterm birth rate and most pregnancies end these days via a planned caesarean section (89). There is still controversy about the appropriate options for anesthesia and analgesia management in SMA patients, as information is limited (88,90). No deleterious effects on fetal or maternal outcome were seen in a series of 13 patients with SMA type III (89). Exacerbation of muscle weakness after the second trimester was experienced by some of these patients, most striking and consistent in women with a presumed autosomal dominant inheritance of proximal SMA (89). Nonetheless, the majority of women emphasized the great personal values of raising children, who were born mostly against medical advice, especially in childhood-onset cases. Recommendations for affected women who plan a pregnancy have recently been established during a workshop organized by the European Neuromuscular Center (ENMC) at the end of 2010 (91).

### 128.2.6 Differential Diagnosis

The differential diagnosis of acute SMA type I comprises the whole spectrum of the floppy infant syndrome, including cerebral malformations, perinatal asphyxia, metabolic defects, Prader–Willi syndrome, Zellweger’s syndrome, mitochondrial disease, and other congenital neuromuscular disorders. A careful neuropsychiatric examination is required to exclude other diseases if SMN1 deletion screening is negative. If there is clear evidence of anterior horn cell disease, the so-called SMA plus variants have to be taken into account as separate genetic entities.

The clinical picture of the mild SMA type III is often indistinguishable from the muscular dystrophies even after neurologic investigations. The neurogenic changes in long-standing SMA courses become less prominent with increasing age, so that a definite diagnosis may be impossible. Families classified as X-linked proximal SMA turned out to have a deletion in the dystrophin gene, confirming X-linked muscular dystrophy. In many

patients with limb-girdle muscular dystrophy, it is now possible to classify the immunohistochemical defect in muscle. If cardiomyopathy is seen in patients with apparent SMA, this should prompt a search for a mutation in the lamin A/C gene and immunostain studies for emerin to exclude the autosomal dominant and X-linked forms of Emery–Dreifuss muscular dystrophy. Lamin A/C gene mutations were seen in 10% of our families with the diagnosis of autosomal dominant proximal SMA (92).

Hexosaminidase A deficiency may rarely produce a clinical picture resembling SMA type III, because signs of cerebellar dysfunction (mainly dysarthria) may appear years after clinical onset. In particular, if atypical features in juvenile-onset SMA are present, a hexosaminidase deficiency should be excluded by laboratory studies (93).

The most important differential diagnoses of SMA type IV are Kennedy syndrome, with an X-linked mode of inheritance (see later), and ALS, which is rarely familial (10–20%) and can be inherited as an autosomal dominant or recessive trait. ALS often starts with pure lower motor neuron signs, but progression of weakness is more rapid and bulbar symptoms usually appear in early stages of the disease. In most cases, there is evidence of upper motor neuron involvement soon after clinical presentation, and this problem should resolve diagnostic difficulties. In occasional cases, upper motor neuron signs are lacking, and a distinction might not be possible. This is underscored by the observation of families with an overlapping SMA/ALS phenotype and marked intrafamilial variability based on VAPB gene (39) or SETX gene mutations (94).

Interestingly, alterations of the SMN genes have been demonstrated in patients with sporadic ALS and with slowly progressive SMA, indicating that deficiency of the SMN protein can also modify the phenotype of adult motor neuron diseases (95–97).

Acid maltase deficiency can also mimic SMA type IV or the Kennedy syndrome, because glycogen accumulation is not always apparent in the biopsied muscle.

In dominant SMA families, proximal myopathic myopathy (PROMM) or myotonic dystrophy type 2 (DM2) has to be considered because changes suggesting neurogenic atrophy may appear in muscle. The presence of myotonia and cataracts, and molecular genetic screening of the expanded CTTG repeat in the ZNF9 gene on chromosome 3 should clarify the diagnosis.

Postpoliomyelitis muscular atrophy is supposed to be due to the lack of an aging motor neuron to nourish an abnormally large number of regenerated sprouts (98) and is a potential cause of diagnostic and genetic confusion.

### 128.2.7 Variants of Childhood Onset (“SMA Plus”)

The applicability of DNA studies in families with childhood SMA makes a separation of classical SMA from variants with atypical or additional features necessary. This issue has been addressed in an ENMC workshop 2001 (99).

**128.2.7.1 SMA with Respiratory Distress, SMARD (Diaphragmatic SMA).** One important differential diagnosis of classic infantile SMA is anterior horn cell disease with initial respiratory insufficiency due to diaphragmatic palsy (diaphragmatic SMA), first described in the 1980s (100). The presenting symptom is acute respiratory distress at birth or soon thereafter, requiring permanent ventilation. Generalized weakness and hypotonia are usually associated with the respiratory distress, whereas distally pronounced weakness becomes evident later in the disease course (Figure 128-15). The chest X-ray study shows eventration or abnormal movements of the diaphragm. Anterior horn cell loss and diaphragmatic atrophy have been confirmed at autopsy in some cases. Because the diaphragm is usually well preserved in proximal SMA, this feature is an important clinical criterion for differential diagnosis (101).

SMARD is a rare autosomal recessive disorder and is genetically heterogeneous. One type (SMARD1) is caused by mutations in the IGHMBP2 gene on chromosome 11q13 (102). After linkage studies excluded SMA 5q, a locus was discovered on chromosome 11q13-q21 that led to the identification of the IGHMBP2 gene, the human homolog of the murine *ighmbp2* gene, which causes the neuromuscular degeneration (*nmd*) phenotype in mice (54). SMARD1 patients of various ethnic backgrounds have been described with mutations in the IGHMBP2 gene, further defining the clinical spectrum of this entity (103–105). Meanwhile, long-term survivors into the second decade under permanent ventilation are reported (101); moreover, some patients do not develop diaphragmatic palsy even years after onset of weakness (106). There is no apparent genotype–phenotype relationship, and mutation screening is hampered by a large gene with numerous polymorphisms. The pathogenic pathway of IGHMBP2 deficiency is still unknown, but there may be a similar involvement in the RNA metabolism like in SMA 5q.

**128.2.7.2 SMA with (Olivo-)Ponto-Cerebellar Hypoplasia.** In patients with pontocerebellar hypoplasia or early

**FIGURE 128-15** Diaphragmatic SMA characterized by initial respiratory failure due to diaphragmatic palsy. Generalized muscular hypotonia and distally pronounced weakness.

atrophy and anterior horn cell involvement, a profound floppiness at birth can be seen, which is followed by mental retardation, multiple joint contractures, and cerebellar signs (vision impairment, nystagmus, ataxia). Life span does not exceed a few months in most instances (107). However, longer survival up to several years has been described (108). The early-onset form of the disease is denoted as pontocerebellar hypoplasia (PCH)-I (109) and is consistent with autosomal recessive inheritance. This rare disorder might be mistaken for severe infantile SMA, especially because electromyography (EMG) and muscle biopsy give evidence of neurogenic changes. Following clinical examinations and negative molecular genetic testing for infantile SMA, brain imaging methods might be helpful to identify cerebellar hypoplasia (Figure 128-16) and more widespread volume loss of pons and brainstem. Postmortem examinations show neuronal depletion in the cerebellar hemispheres and vermis, and may include the pons and olivary nuclei in addition to anterior horn cell degeneration. Neuronal loss in other parts of the spinal cord, basal ganglia, and brainstem suggest a more widespread neuronal degeneration, at least in a subgroup of patients. Linkage with chromosome 5q markers has been excluded in two families, and the results of genome scan approaches are awaited for families corresponding strictly to PCH-1. In 2012, mutations of the EXOSC3 gene were discovered as the major cause for PCH-1 of variable severity (110). EXOSC3 is a core component of the human RNA exosome complex. PCH-1 is the first disease found to be associated with a dysfunction of an RNA exosome core component. Further genotype-phenotype studies confirmed biallelic mutations in 10 of 27 (37%) families collected worldwide (111).

**128.2.7.3 SMA with Arthrogryposis Multiplex.** Arthrogryposis multiplex is a heterogeneous group of neuromuscular disorders. A neurogenic type is caused by anterior horn cell degeneration and leads to severe muscle weakness similar to SMA type I and congenital contractures. Although the majority of cases are believed to be nonprogressive and nonfamilial, there are patients with more

complex pathology that follows autosomal recessive or X-linked traits.

In some patients, the clinical picture of severe SMA is combined with contractures and congenital fractures of the long bones; this phenotype has been thoroughly described by Borochowitz and colleagues (112). Anterior horn cell involvement and neuronal degeneration in other parts of the CNS can be seen pathoanatomically. In extremely rare cases with congenital SMA 5q, fetal weakness can lead to congenital contractures with bone fractures and early lethality (see section on Genotype-Phenotype studies). The majority of patients with neurogenic arthrogryposis multiplex congenita have a different genetic background, as linkage analysis with chromosome 5q markers excluded the gene locus for childhood SMA in most families with autosomal recessive inheritance. The underlying gene defects are as yet unknown.

Because there is a preponderance of males, a significant proportion of cases might be X-linked. One convincing form of an X-linked infantile SMA is associated with arthrogryposis, genital abnormalities, and facial dysmorphism (113). This syndrome gene was mapped to Xp11.3-q11.2 and mutations were found in the UBE1 gene (114).

Autosomal dominant forms of congenital arthrogryposis in combination with lower motor neuron disease of milder course are also reported (115,116). The gene for one Dutch family was mapped to the long arm of chromosome 12 with evidence of heterogeneity (117), before mutations were found in the TRPV4 gene (118).

**128.2.7.4 SMA and Myoclonic Epilepsy.** The combination of infantile SMA and myoclonic epilepsy has rarely been reported. It was first described as an autosomal dominant disease with distally pronounced weakness (119), but subsequent cases showed a more proximal or generalized pattern of muscle atrophy and recessive inheritance (120). The patient described by Lance and Evans (121) had bilateral hearing loss associated with action myoclonus, ataxia, and SMA. Normal intelligence and neurogenic findings on EMG and muscle biopsy are cardinal diagnostic findings; the genetic basis remains to be identified. Mitochondrial disease, metabolic, and lysosomal disorders must be excluded.

**FIGURE 128-16** SMA and pontocerebellar hypoplasia in a 9-month-old boy who was initially thought to have Werdnig–Hoffmann disease and finally showed biallelic mutations of the EXOSC3 gene.

## 128.3 NONPROXIMAL SPINAL MUSCULAR ATROPHY

### 128.3.1 Distal

Distal SMA or distal HMN comprises a group of genetically and clinically heterogeneous disorders. In a population survey in northeast England, distal SMA accounted for about 10% of all cases (122). Both autosomal dominant and recessive genes cause childhood- and adult-onset forms, which normally have a chronic and benign course. X-linked distal SMA is very rare, and only described in a large Brazilian family (123).

**FIGURE 128-17** Distal SMA. Denervation atrophy of the calves (A) and the forearm and hand musculature (B) in a 9-year-old boy.

**128.3.1.1 Clinical Picture.** The early-childhood form of distal SMA starts soon after birth with distal hypotonia and wasting, and leads to pes planus and sometimes scoliosis within the first years of life. Despite considerable handicap due to weakness of the hands (Figure 128-17), these patients' scholastic and occupational attainments are often better than expected. Juvenile- and adult-onset distal SMA is usually characterized by slowly progressive weakness and wasting of the extensors muscles of the toes and feet. Later on, weakness and wasting also involves the distal upper limb muscles. Progression can be variable; some patients become wheelchair bound, and some develop respiratory insufficiency. There are different distal SMA subtypes defined by additional findings, such as vocal cord palsy, spasticity, pyramidal tract signs (ALS-like features) and diaphragmatic palsy (Table 128-4).

**128.3.1.2 Differential Diagnosis.** The differential diagnosis of distal SMA includes hereditary motor and sensory neuropathy (HMSN) or Charcot–Marie–Tooth (CMT) disease and HMN, which are much more common than distal SMA. The clinical picture may be indistinguishable if overt sensory disturbances are absent. Therefore, it is important to exclude peripheral nerve involvement by electrophysiologic investigations or DNA studies before diagnosing distal SMA. Sensory disturbances, abnormal sensory nerve action potentials, and markedly reduced nerve conduction velocities indicate polyneuropathies and exclude the diagnosis of SMA. Because the list of genes causing variable phenotypes, including polyneuropathies, axonopathies, and complex motor neuron diseases, is still growing, a subdivision becomes increasingly difficult (124,125).

Distal SMA must also be distinguished from distal myopathy. Either the high serum CK level or muscle biopsy studies that include immunocytochemical and immunoblot analyses or, in some instances, DNA studies will help to exclude Miyoshi distal myopathy, dysferlinopathy, hereditary inclusion body myopathy, tibial muscular dystrophy, or Welander dystrophy. In nonfamilial cases of distal SMA, intraspinal pathology, for example, ependymoma or lumbar stenosis, must be excluded by magnetic resonance imaging (MRI).

**128.3.1.3 Genetics.** Following epidemiologic studies from northeast England, autosomal recessive inheritance of distal SMA is more frequent (~75% of cases) than autosomal dominant inheritance (122). A heterozygosity frequency of 1:100 has roughly been estimated for

a childhood- and an adult-onset genes (122). Whether these data are valid for all types of distal SMA or hereditary motor neuropathies must be clarified, because dominant new mutations play an important role at least in HMSN (CMT neuropathies).

In case of parental consanguinity or sibships with multiple affected siblings, autosomal recessive inheritance with 25% recurrence risk is most likely. For siblings of sporadic cases, a risk of 1:4 should be given, although it is probably significantly smaller. Children of affected subjects have a risk of about 1:8, because dominant inheritance cannot be excluded even in patients whose parents show no signs of distal SMA.

The 17 affected men of the rare X-linked form (123) had an age at onset in the first decade, and the first presenting symptom was foot deformity or gait instability, followed by distal lower limb weakness. Finally, the hands were affected. Disease progression was slow; all patients remained ambulant. The gene defect was assigned to Xq13.1-q21 and a few years later, mutations in the ATP7A gene were identified (126).

Similar to HMSN, distal SMA shows clinical and genetic heterogeneity (for review, see References (124,125)). With increasing knowledge of the genetic basis and overlapping phenotypes, the distinction between distal SMA, HMN, and CMT neuropathy becomes less clear and hampers classification approaches. The gene defects in most distal SMAs remain to be determined, although many genes have been identified until the end of 2010 (Table 128-4). The SMN1 gene does not play a role for pathogenesis. In a large patient cohort with distal HMN/SMA pathogenic mutations were found in 17 out of 112 index patients in four genes (BSCL2, HSPB8, HSPB1, SETX), resulting in an overall diagnostic yield of 15% and of 30% in the subgroup of families with autosomal dominant inheritance (125). In summary, genetic testing of BSCL2 is recommended in patients with distal HMN showing the only two known mutations in 5–10% of patients, in particular if a variable degree of upper motor neuron signs is present.

**128.3.1.4 Juvenile Distal-Type Hirayama.** Juvenile distal SMA is also known as “monomelic juvenile SMA type Hirayama,” “benign monomelic amyotrophy,” or “juvenile segmental SMA.” It has first been reported in Japanese literature (127) but was later found in many populations. Sporadic occurrences have been reported in more than 200 cases, with a large predominance of men. The onset is insidious and usually occurs usually between 15 and 25 years of age. The cardinal features are asymmetric wasting and weakness confined to a single upper limb (hand and forearm), which might spread to the contralateral or lower limb. The condition is very benign with an initial progressive phase coming to a halt within 2–4 years after onset in most cases. Bulbar, sensory, and pyramidal signs are lacking so that motor amyotrophy is likely. A postulated pathogenesis is circulatory insufficiency due to chronic compression of the spinal cord (128). Other authors are of the opinion that the focal spinal cord compression is flexion induced. MRI studies and spinal

**TABLE 128-4 Genetic Classification of Distal SMA (Hereditary Motor Neuropathy (HMN) and Its Variants) (2010)**

Mode of Inheritance	Type (OMIM)	Clinical Features	Gene Locus (Gene)
Autosomal dominant	Distal HMN I (182960)	Distal weakness starting in the lower limbs, onset in childhood and youth (median 10 years), involvement of the upper motor neuron described (juvenile ALS)	7q34-q36
	Distal HMN II/CMT2L/CMT2F (158590)	Distal weakness starting in the lower limbs, variable age at onset, rapid progression, sensory nerve involvement described (CMT2L/CMT2F)	HMNIIA: 12q24.3 (HSP8) HMNIIB: 7q11-21 (HSP1)
	Distal HMN V/CMT2D (600794)	Distal weakness starting in the hands, later spreading to the lower limbs, onset in youth or adolescence, sensory nerve involvement described (CMT2D)	7p15 (GARS)
	Distal HMN with spasticity/Silver syndrome (606158)	Variable clinical picture corresponding to HMN I, II, or V, mild to severe spastic pareses (may not be present), onset in youth or adolescence	11q12-14 (BSCL2)
	Distal HMN VII/HMN7B/SMA with vocal palsy (158580, 608465)	Distal weakness predominantly of upper limbs, onset from childhood to adulthood, hoarse voice, stridor, vocal cord changes, facial weakness described	HMN7A: 2q14 HMN7B: 2p13 (DCTN1)
	Distal HMN with pyramidal tract signs/ALS4 (608465)	Distal and proximal weakness starting in the lower limbs, onset mostly in youth or adolescence, brisk reflexes, positive Babinski sign	9q34 (SETX)
	Congenital distal SMA (600175)	Congenital distal muscle wasting and weakness of the lower limbs associated with contractures, scoliosis, no progression	12q23-34 (TRPV4)
Autosomal recessive	Distal HMN VI/SMARD I/DSMA1 (604320)	Starting with generalized muscular hypotonia, later distal weakness, onset mostly in the first months of life, sudden respiratory distress due to diaphragmatic palsy	11q13.2-13.4 (IGHMBP2)
	Distal HMN of Jerash type/DSMA2 (605726)	Distal weakness starting in the lower limbs, onset in youth to adulthood, brisk reflexes, positive Babinski sign	9p21.1-12
	Distal HMN III/HMN IV/DSMA3 (607088)	Distal weakness starting in the lower limbs, onset in childhood or youth, variable progression, diaphragmatic palsy may be present	11q13.3
	Distal HMN/distal SMA/DSMA4 (611067)	Distal weakness with rapid progression, onset in the first years of life, early immobilization and respiratory insufficiency	1p36 (PLEKHG5)
X-linked	Juvenile distal SMA/adult-onset distal SMA (300489)	Distal weakness starting in the lower limbs, onset variable in childhood to adolescence, slow progression	Xq13.1-q21 (ATP7A)

CMT, Charcot–Marie–Tooth disease; HMN, hereditary motor neuropathy; SMA, spinal muscular atrophy; ALS, amyotrophic lateral sclerosis.

angiography argue against this and support the view that Hirayama's disease is an intrinsic motor neuron disorder (129,130). If there is evidence of spinal cord compression, typical juvenile distal SMA has most likely to be regarded as nongenetic.

Some cases of segmental SMA are familial (131), and some have an asymmetrical but progressive weakness that can be either distal or proximal. To clarify the variants of the chronic monomelic amyotrophy syndrome, Serratrice (132) classified three subgroups, including

(i) a benign, nongenetic form due to focal amyotrophy, restricted to young men; (ii) a more progressive and sometimes familial form affecting either an upper or a lower limb; and (iii) patients with recurrent episodes of monomelic atrophy. Molecular genetic screening for SMN1 gene alterations showed no evidence of a modifying influence (133,134).

There are no distinctive findings in segmental SMA. If spinal pathology has been ruled out by imaging studies, only long-term observation over many years might point toward the correct diagnosis. The differential diagnosis includes, for example, distal SMA or HMN, multifocal motor neuropathy, inclusion body myositis, dysferlinopathy, and early myotonic dystrophy.

### 128.3.2 Scapuloperoneal SMA

Autosomal dominant familial SMA with scapuloperoneal involvement and adult onset was first described by Stark (135) and Kaeser (136), but the original family later turned out to be a desmin myopathy due to a heterozygous mutation in the DES gene (137). A rare autosomal recessive form also exists (1). The German eponym SMA type Vulpian-Bernhardt, which has been used to denote a heterogeneous group of disorders, should be avoided.

The clinical manifestations are variable. Weakness may first appear in the foot and toe extensors, and then spread to the shoulder girdle and the proximal muscles of lower limbs. Tendon reflexes are diminished, and fasciculations are present. The dominant form usually presents in adolescence or early adult life (138,139); the recessive form tends to present earlier and shows a more progressive course (1,140). Since the literature has become sparse on the subject in the past 20 years, the relevance of this entity among the SMAs remains doubtful.

Because facio-scapulo-humeral muscular dystrophy (FSHD) can be clinically indistinguishable from scapuloperoneal SMA and may show changes suggesting denervation in muscle, scapuloperoneal SMA can be diagnosed only after FSHD has been excluded by DNA analysis.

Some patients with scapuloperoneal weakness also have cardiac conduction defects. The clinical distinction from autosomal dominant or X-linked Emery-Dreifuss muscular dystrophy can be difficult; therefore, a thorough investigation and molecular studies are required before diagnosing SMA plus cardiomyopathy.

There is a rare and clinically highly variable subtype of autosomal dominant SMA, which has previously been classified as scapuloperoneal SMA (OMIM 181405) and is characterized by congenital absence of muscles, progressive scapuloperoneal atrophy, laryngeal palsy, and progressive distal weakness and atrophy (141). This distinct entity turned out to be allelic to a congenital benign form with joint contractures caused by mutations of the TRPV4 gene on chromosome 12q23-34 (OMIM 60015) (142,143).

### 128.3.3 Progressive Bulbar Palsy

Progressive bulbar palsy is extremely rare and generally categorized into childhood- and adult-onset forms. The eponym Fazio-Londe disease has been used for the autosomal recessive type of childhood onset, although the family reported by Fazio (144) followed an autosomal dominant pattern.

In the childhood form, first signs of facial weakness and dysarthria are present between 2 and 14 years of life. Subsequently, dysphagia, respiratory insufficiency and involvement of other cranial nerves develop with a rapid progression. Death occurs in most cases within a few years after onset. Autosomal recessive and dominant pedigrees have been described.

There are juvenile- and adult-onset forms that are very rare and follow an autosomal dominant mode of inheritance (145,146). Since the majority of patients with the diagnosis of progressive bulbar palsy progress to a clinical picture designated as ALS (147), the classification as a separate disease entity is difficult as long as the pathogenesis or the genetic basis is unknown.

The Brown-Vialetto-Van Laere syndrome is characterized by bulbopontine paralysis and bilateral nerve deafness (Figure 128-18). The age at onset ranges from birth to adulthood, with a median of 13 years. According to Sathasivam (148) progressive hearing loss is the presenting sign in the vast majority of cases. The weakness is in the distribution of motor cranial nerves III, and VII to XII; scapuloperoneal or distal muscle atrophy occurs

**FIGURE 128-18** Brown-Vialetto-van Laere syndrome in a 14-year-old boy a few months before he died. Note facial weakness with severe ptosis. Following bulbar dysfunction, he developed scapuloperoneal atrophy.

later in the disease course. Progression is variable, and life span is reduced because of respiratory complications caused by diaphragmatic palsy. About half of the cases are sporadic, and the majority of the familial cases are autosomal recessively inherited. Recently, mutations in the C20orf54 gene were detected in seven unrelated families (149), which can produce a metabolic profile mimicking mild multiple acyl-CoA dehydrogenation defect (MADD) (150). Another family was suggestive of an autosomal dominant pattern with variable expressivity (151) but this awaits further confirmation.

### 128.3.4 Spinobulbar Neuronopathy (Kennedy Syndrome)

An important differential diagnosis of late-onset SMA in association with bulbar palsy and gynecomastia is spinobulbar atrophy type Kennedy (152). The mean age at onset is 30–40 years (range 15–60 years); however, there is an average delay of the correct diagnosis of about 5 years (153). Clinically, there are pronounced muscle cramps and fasciculations accompanying predominantly proximal and symmetrical weakness that affects the legs more than the arms. Facial and perioral contraction fasciculations and postural tremor of the hands are frequently observed. There are often signs of partial androgen insensitivity, with gynecomastia, impotence, testicular atrophy, and reduced fertility. Androgen levels and strength are inversely correlated with age. As yet, there are no prospective hormonal intervention studies that gave conclusive results, despite the fact an antiandrogen treatment in animal models proved to be efficient (153).

Involvement of the sensory neurons is usually subclinical, but can be detected by electrophysiologic investigations. Dysarthria, dysphonia, and dysphagia result from progressive degeneration of spinal and bulbar motor neurons. The serum CK level is often markedly elevated (>35-fold above the upper normal limit). Life expectancy can be shortened by aspiration pneumonia. The disease is X-linked and has a prevalence of about 1:40,000. Female carriers may manifest with cramps, mild muscle weakness and fasciculations (154,155). Kennedy disease is caused by a CAG repeat expansion of the androgen-receptor gene (156). The diagnosis is confirmed when there are more than 40 CAG repeats, whereas there is only a weak inverse correlation between the number of repeats and the age of onset severity of the clinical picture (157,158).

## 128.4 MANAGEMENT

A curative treatment of SMA is not yet available, but the knowledge of the genetic defect in SMA 5q currently has a major impact on therapeutic strategies. Because an increased number of SMN2 copies might partly

compensate for or prevent the motor neuron loss, agents that enhance the production of the SMN protein might be a means of therapy. Strategies include (i) upregulation of SMN expression either by stimulation of promoter activity or by enhancement of exon 7 inclusion of the SMN2 gene, (ii) gene therapy to supply extra copies of a functional SMN gene or the SMN cDNA in motor neurons, or (iii) compensation of the functional consequences caused by SMN deficiency (for review see Reference (159)).

The upregulation of SMN2 gene transcription has been intensely studied for about a decade after identification of histone deacetylase inhibitor Htra-beta1 (160). Several splice enhancers have entered clinical trials, a summary of completed and ongoing clinical trials by 2008 was given by Lunn and Wang (51). By 2010, only few randomized, double-blind, and placebo-controlled trials were published and did not demonstrate a therapeutic effect of splice enhancers. This applies to phenylbutyrate in SMA type II (161) and to valproic acid and L-carnitine in a nonambulatory cohort of SMA patients (162). At the time of this writing (February 2011), no medication is known that has a proven positive influence on the course of the disease.

The development of ASO therapy in SMA has been reviewed by Burghes and McGovern (163). ASOs can be used to alter splicing of a gene and either restore or eliminate protein products. Since it was shown in a mouse model (60) that restoration of SMN was achieved by ASO blocking, it is hoped that this could be used for clinical trials in SMA; however, there is still limited information on the different chemistries of ASOs and their action in the nervous system. The same applies to stem cells approaches that await further studies before entering clinical practice (159).

The main therapeutic elements in SMA are physical and orthopedic therapy and ventilatory support (164). Goals of physiotherapy are prevention of contractures and, in the milder types, the maintenance of mobility and ambulation as far as possible. Contractures may be treated by passive mobilization and stretching (Figure 128-19). Preliminary results of studies using isometric strength training in mild SMA have at least given some evidence of a beneficial effect. At its present state, electrical stimulation cannot be recommended as a therapeutic tool.

Main orthopedic problems in early-onset SMA are inability to sit, contractures of lower limbs, and scoliosis. Orthopedic treatment includes conservative methods (orthotic devices and physiotherapy) as well as surgical procedures for the limbs and spine.

Respiratory failure is common in SMA patients—treatment is similar to that in other neuromuscular disorders, with a major role for assisted ventilation. Noninvasive methods of intermittent ventilation is recommended in chronic or late-onset forms of SMA (Figure 128-20) and increasingly offered to patients with severe SMA type I.

**FIGURE 128-19** SMA type II patient with severe contractures that are treated by passive mobilization and stretching.

**FIGURE 128-20** Intermittent noninvasive ventilation in a 32-year-old SMA type II patient. The ventilator is fixed at the back of the electric wheelchair to allow a maximum mobility.

### Biography

**Sabine Rudnik-Schöneborn** is a senior lecturer in human genetics with a medical background holding a permanent position as a professor for clinical genetics at the Institute for Human Genetics, Medical faculty, RWTH Aachen, Germany. **Klaus Zerres** is professor and head of the Institute for Human Genetics, Medical Faculty, RWTH Aachen, since 1999. He is also a medical doctor trained in human genetics. Our group has been engaged in the clinical description and genetic characterization of spinal muscular atrophies (SMA) for more than two decades. In addition, we studied reproductive issues of women with neuromuscular disorders in a similar time frame. After identification of the gene defect (SMN1 gene) for classical proximal SMA in 1995, we early focused on the genetic characterization of SMA-plus types. Within the framework of the International SMA Consortium and the European Neuromuscular Centre (ENMC) we contributed to the definition of diagnostic criteria, the classification of disease variants and the identification of disease genes. We were involved in identifying the gene for SMA and respiratory distress (SMARD1) and performed genotype-phenotype studies thereafter. On the basis of a large collection of families with SMA and pontocerebellar hypoplasia (PCH-1), we recently identified the EXOSC3 gene as the major gene defect together with the group of Joanna Jen, University of California, Los Angeles, USA, and broadened the clinical spectrum. We were first to give pathoanatomical evidence of a sensory nerve involvement in SMA, and moreover we defined congenital heart disease and vascular dysfunction as a feature of severe SMA. We reviewed genotype-phenotype correlations in infantile SMA in German patients in order to provide reliable data on natural disease course and clinical variability as a basis for clinical trials.

## Hereditary Muscle Channelopathies

*Frank Lehmann-Horn, Reinhardt Rüdel, and Karin Jurkat-Rott*

Neurosciences Division of Neurophysiology, Ulm University, Ulm, Germany

### 129.1 INTRODUCTION

Defective ion channels may play a causal role in disease pathogenesis. This implication was first concluded from the observation of an abnormal ion conductance in muscle fibers biopsied from myotonic goats (1). In man, a similar conclusion was reached for patients with paramyotonia congenita and periodic paralyses (2,3). The term “ion channelopathies” was then coined in the 1990s (4), and defined for disorders that are caused by malfunction or altered regulation of ion channel proteins. Channelopathies can, therefore, be either hereditary or acquired (usually caused by autoantibodies).

Hereditary channelopathies can be categorized as those affecting the motor end plate (congenital myasthenic syndromes (CMS)), the sarcolemma (myotonias and periodic paralyses) and excitation–contraction coupling (malignant hyperthermia (MH), central core myopathy and multiminicore myopathy). The channel defects result in changes of excitability that one would expect to be constantly present. Fortunately, this is not the case. Clinical symptoms mainly appear episodically, provoked by an out-of-the-normal situation, a so-called trigger (5). Compensatory mechanisms such as the normalization of the serum potassium level often allow an episode to cross over to complete remission. In addition to the episodes, progressive manifestations with muscular degeneration are present in a substantial percentage of patients.

The total prevalence of monogenic muscle channelopathies is about 5:100,000, i.e. they are rare diseases. Pharmacogenetic influences on abnormal muscle channels, which may generate the susceptibility to MH, increase the clinical relevance of channelopathies considerably. As many disease mechanisms have been elucidated by functional characterization on the molecular level, the channelopathies are regarded as model disorders. Molecular genetics identify the underlying mutations and thus often enable one to predict the course of the diseases and to assign an individual therapy for the patient. They also allow one to calculate the patient’s risk of having affected offspring.

### 129.2 ELECTROPHYSIOLOGY OF CLINICAL WEAKNESS AND PARALYSIS

The excitability of a muscle fiber, and thus its ability to generate force and contraction, depends on a *high* resting potential across its sarcolemma (−80 mV inside with respect to outside). Such fibers are assuming the P1 state in the nomenclature of Jurkat-Rott et al. 2009 (6), and they make up the majority of the fibers in a healthy muscle. Owing to the complicated voltage dependence of the membrane conductance on the membrane potential, muscle fibers can also assume a *low* stable resting potential of about −60 mV. Such “depolarized” fibers are said to be in the P2 state and their major functional difference is that they cannot be excited and, therefore, are “paralyzed”. In a healthy muscle, fibers in the P2 state make up only a small minority. Mutations in the genes encoding the various ion channels responsible for the membrane potential may influence the electrical stability so that fibers can shift from the P1 state to the P2 state—not only for short time intervals but also for very long durations. The number of excitable fibers is then very much reduced.

### 129.3 HEREDITARY CHANNELOPATHIES AFFECTING THE END PLATE

#### 129.3.1 Congenital Myasthenic Syndromes

Of the myasthenic disorders, the CMS are the rarest, affecting the neuromuscular transmission of up to three individuals per million. Like the autoimmune disease myasthenia gravis, the myasthenic syndromes are characterized by defective excitation causing muscle fatigue (7,8). Although rare, they form a very heterogeneous group of inherited disorders. They arise from mutations affecting presynaptic, synaptic or postsynaptic proteins at the neuromuscular junction on which synaptic formation and function depend. The majority are recessively inherited. Detection of the genetic defect is important for the selection of the appropriate drug therapy (Table 129-1).

Although anticholinesterase medication is beneficial in most forms, it can be deleterious in others.

**129.3.1.1 Clinical Symptoms.** Weakness is usually evident at birth or within the first or second year of life, and results in feeding or breathing difficulties, ptosis, ophthalmoplegia, and delayed motor milestones. Strength sometimes improves during adolescence. In about 15% of the cases, the weakness does not become evident before adolescence or even adult life. A major group of patients show a limb girdle pattern of muscle weakness that can be mistaken for a myopathy (9). These muscles have small, simplified neuromuscular junctions but normal acetylcholine receptor and acetylcholinesterase function. Reflexes are usually brisk and muscle wasting does not occur. Congenital arthrogryposis multiplex may be present involving reduced fetal movement and multiple joint contractures in the neonate (10).

The slow-channel syndrome is the only disease of this group that presents in childhood, adolescence or particularly adult life, with upper limb predominance and contractures. Patients show an increased synaptic response to acetylcholine with characteristic repetitive discharges in response to a single supramaximal stimulus. It is aggravated by cholinesterase inhibitors and is progressive.

A CMS channelopathy so far identified only in a single family affects the skeletal muscle sodium channel Nav1.4 encoded by *SCN4A* (11). Another CMS also observed only in one family is caused by a mutation in *MUSK* on chromosome 9q31.3-q32 that encodes MuSK, a muscle-specific kinase.

A rapsyn defect causes either mild generalized muscle weakness of late onset, fluctuating ptosis and intermittent double vision or life-threatening episodes of early-onset

<sup>c</sup>Susceptibility in world population.

is haploinsufficient. The reduced availability of sodium channels decreases the safety factor of synaptic transmission and thereby causes myasthenic syndrome (11).

Other postsynaptic CMS are caused by a rapsyn defect due to loss-of-function *RAPSN* mutations (17). Rapsyn plays a key role in acetylcholine receptor clustering during development, and is another relatively frequent cause of CMS. Recessive Dok-7 mutations also result in a defective structure of the postsynaptic membrane. The p.N88K rapsyn mutation and the c.1124\_1127dupTGCC duplication in *DOK7* are frequent in Europe. Recently, mutations in *GFPT1* encoding the glutamine-fructose-6-phosphate transaminase 1 have been identified in this also recessive CMS type. Consistent with these data, downregulation of the *GFPT1* ortholog *gfpt1* in zebrafish embryos altered muscle fiber morphology and impaired neuromuscular junction development. *GFPT1* is the key enzyme of the hexosamine pathway yielding the amino sugar UDP-*N*-acetylglucosamine, an essential substrate for protein glycosylation (18).

## 129.4 HEREDITARY CHANNELOPATHIES AFFECTING THE PLASMALEMMA

### 129.4.1 Nondystrophic Myotonias

**129.4.1.1 Clinical Symptoms.** The major symptom of the myotonias is a generalized muscle stiffness that appears particularly following strong and/or sudden muscle contractions, e.g. when a patient gets scared. The stiffness is caused by series of involuntary action potentials that can occur in practically all skeletal muscle fibers. The muscles are often hypertrophied, in contrast to what is seen in most other muscle diseases. The involuntary action potentials are caused by one (or two in the case of recessive Becker myotonia) of a great number of mutations in genes encoding muscular ion channels, which all result in increased excitability of the sarcolemma. Depending on the type of channels affected, chloride and sodium channel myotonias are distinguished (19) (Table 129-1).

There are two forms of chloride channel myotonia, the rare dominant Thomsen myotonia and the more common recessive Becker myotonia. Both forms are characterized by generalized myotonia and the so-called warm-up phenomenon, a reduction of myotonia in the course of repeated contractions. A typical feature of myotonia would be the inability to let go after a hearty handshake. Such myotonia during closure of the fist is most pronounced when the muscles have remained relaxed for at least 10 minutes. Another typical sign is the “lid-lag” phenomenon, whereby after a brief look upward, upon a brisk look downward the eyelids do not immediately follow the eyeballs because of muscle stiffness. Gentle tapping on a relaxed muscle may elicit a “myotonic reaction”, a local muscle contraction called “percussion myotonia.” A distinct myotonia may be followed by a “transient weakness” of the same muscle. This weakness

hampers the patient more than the stiffness (20,21). Hypertrophy is more pronounced with the Becker than with the Thomsen form, whereby the glutei, the femurs and the calves are most affected. Paradoxically, the power produced by these muscles is less than expected. In severe cases the hyperactivity will result in shortened muscles leading to pes equinus with consequent lordosis and in a reduced extension of the elbow and wrist joints. Males are usually more affected than females. Females often develop myotonic symptoms only after hypothyreosis or gravidity. In Becker myotonia, myotonic stiffness is usually first detected within the rather long time span between first school enrollment and the third decade of life. During adulthood the severity of myotonia remains constant; life expectancy is normal. Becker patients have reduced manual skills; this should be given consideration when occupational choices are made.

The sodium channel myotonia is also called potassium-sensitive myotonia because the myotonic stiffness is increased after oral intake of potassium (c. 1 hour after 1–2 potassium tablets). Depending on the mutation, symptoms may occur in a wide range of severity. The most benign form is called myotonia fluctuans (22), and the most severe form myotonia permanens (23,24). With myotonia fluctuans work-induced stiffness does occur, however, usually with a delay of about an hour. It then lasts for about 1–2 hours. The typical warm-up phenomenon is often masked by this delay, but with repeated contractions and relaxations of the extremities it may be observed. Patients having myotonia permanens may be more or less immobile by the continual activity in many of their muscles. With these patients a diagnostic test applying oral potassium must not be performed because of the danger that stiff respiratory muscles lead to respiratory insufficiency (25). Patients with sodium channel myotonia tend to suffer from cramping when their muscles are being stressed (26).

For a clinical discrimination between chloride and sodium channel myotonia one may use the fact that chloride channel myotonia shows warm-up of the eyelid muscles, whereas sodium channel mutations cause paradoxical eyelid myotonia (25,27,28). Further specification is possible by investigating the reactions to cold and potassium. For instance, after cooling of an eye for 10 minutes with an ice bag, a forceful closure of the eye may lead to the inability to open for many seconds. Creatine kinase (CK) values of five times the norm may be observed in sodium channel myotonia, whereas in chloride channel myotonia they are at the most a little increased. Some patients, in particular those with a sodium channel myotonia, suffer from muscle pain that increases with the amount of muscle work.

**129.4.1.2 Clinical Neurophysiology.** Typical signs of all types of myotonia are bursts of discharges in the EMG that are elicited by the movement of the needle or by tapping on the muscle. In addition, sodium channel myotonias show long-lasting series of fibrillation

potentials. Like with myasthenia gravis at 3Hz, repetitive nerve stimulation at 10Hz yields a decrement in chloride channel myotonia, but in contrast to myasthenia, the decrement begins later, is more pronounced, not antagonized by tensilon, and runs parallel with the described transient weakness, i.e. the amplitude recovers with continuing stimulation (29). No decrement is found in sodium channel myotonia.

**129.4.1.3 Pathogenesis.** The mutations responsible for the myotonias are located in the genes *CLCN1* and *SCN4A* encoding the muscular chloride and sodium channels, respectively. Both chloride channel myotonias (Becker and Thomsen forms) have in common that the mutations lead to decreased activity of the chloride channels in the sarcolemma, which reduces the chloride conductance of the latter. Physiologically the chloride conductance of a muscle fiber comes up to 80% of the total membrane conductance at rest. This resting conductance is passive ("ohmic"), and its rather high value is very important for a stabilization of the muscle fiber's resting potential of the P1 state close to  $-80$  mV. When the chloride conductance is lower than 30% of the total membrane conductance, the muscle fibers still stay favorably in the P1 state at rest, but they become hyperexcitable. Clinically, this results in myotonia (30). During the state of transient weakness, an increased number of muscle fibers is believed to stay

in the P2 state at the end of a myotonic series of action potentials.

Mutations of the muscular chloride channel gene with dominant and recessive mode of inheritance are responsible for Becker and Thomsen type myotonias, respectively (31) (Figure 129-2). Functionally, the approximately 10 dominant mutations exert a dominant-negative effect on the homodimeric channel complex as shown by coexpression studies, meaning that mutant/mutant and mutant/wild-type complexes are malfunctional. The most common feature of the resulting chloride currents is a shift of the activation threshold toward less negative membrane potentials almost out of the physiological range (32,33). As a consequence, chloride conductance is drastically reduced in the vicinity of the resting membrane potential. Interestingly, both testosterone and progesterone rapidly and reversibly exert a similar effect on chloride conductance (34). The approximately 100 recessive mutations do not functionally hinder the associated subunit. This explains why two mutant alleles are required to reduce chloride conductance sufficiently for myotonia to develop clinically in Becker myotonia. Heterozygous carriers of a recessive mutation are healthy but may exhibit some myotonic runs in the EMG.

Dominant mutations in the gene encoding the muscular voltage-dependent sodium channel Nav1.4 are

**FIGURE 129-2** Membrane topology model of the CLC1 monomer. The functional channel is an antiparallel assembled homodimer. The channel is functional without any other subunits. Symbols are used for the mutations leading to either dominant or recessive myotonia congenita. The amino acids at which substitutions occur are indicated by one-letter abbreviations and numbered according to the protein sequence.

responsible for sodium channel myotonia (22,24,35) (Figure 129-3). The pathogenesis is based on the fact that mutant Nav1.4 channels have a reduced refractory time and this may generate series of action potentials as a consequence (24,36,37). Recently, aberrant splicing has been reported to cause sodium channel myotonia (38).

**129.4.1.4 Epidemiology.** The prevalence of Thomsen myotonia is now estimated at approximately 1:400,000 (25), i.e. much lower than the 1:23,000 of the premolecular era (39). This is owing to the fact that many families with dominant myotonia are now identified as having sodium channel mutations that result in a different disease with very similar symptomatology. Other families were found to have Becker myotonia with pseudodominant inheritance. Conversely, the prevalence of Becker myotonia is now thought to be 1:24,000 (25,40), much higher than Becker's original estimate of 1:50,000 (39). This suggests that the prevalence of a single recessive *CLCN1* mutation is 1:78.

## 129.4.2 Paramyotonia Congenita

**129.4.2.1 Clinical Symptoms.** Paramyotonia is a sodium channel myotonia that, depending on the specific mutation, may or may not also show characteristics of hyperkalemic periodic paralysis (Table 129-1, Figure 129-3). Typically, the myotonic stiffness is negligible in warm muscles, but may assume very cumbersome degrees during exposure

of the muscles to cold. A slight cold draft may suffice to “freeze” the musculature. The warm-up phenomenon might be present in some muscles; however, repeated contractions usually rather increase the muscle stiffness (“paradoxical myotonia”). With extended duration of cooling, the stiffness tends to give way to weakness, which then can last for hours, even after warming the muscles. The mentioned periods of generalized paralysis experienced by patients with certain mutations may occur at rest and in a warm environment.

**129.4.2.2 Clinical Neurophysiology.** In patients with myotonia in a warm environment, there are myotonic bursts and myotonic after-activity reveals a warm-up phenomenon. In patients without myotonia in a warm environment, electrical discharges in the EMG may be absent at normal or increased temperature, but occasional myotonic runs do occur. On cooling, a fibrillation-like spontaneous EMG activity develops consistently, which is maximal at a muscle temperature of about 29°C. With a further drop in temperature, this spontaneous activity decreases and also voluntary activity almost disappears at 24°C when the muscle gets paralyzed. Consequently, compound action potential (CMAP) amplitudes decrease upon cooling, corresponding to the developing weakness.

**129.4.2.3 Pathogenesis.** Most paramyotonia mutations are situated in protein parts relevant for channel inactivation, in the inactivation gate itself (i.e. the intracellular loop connecting domains III and IV like

**FIGURE 129-3** Cartoon of the alpha subunit of the voltage-gated sodium channel Nav1.4 indicating all known mutations responsible for potassium-sensitive myotonia (PAM), paramyotonia (PMC) and hyper- (HyperPP), normo- (NormoPP), and hypokalemic periodic paralysis type 2 (HypoPP2). The alpha subunit consists of four almost homolog domains (repeats I–IV), formed by six transmembrane alpha-helical segments (1–6). Within the membrane, the four domains are so arranged that they form a central pore with segments 5 and 6 lining its wall. The segments 4 contain several positively charged amino acids (arginine and lysine), which are responsible for the voltage sensitivity of the channel. The intracellular loop between domains III and IV represents the channel's inactivation gate. Also domain IV is important for the inactivation process. All the HypoPP mutations replace the arginines within the voltage sensors by neutral amino acids (which are given in the three-letter code, e.g. Arg for arginine). Likewise, HypoPP1 is caused by neutralizing Arg substitutions within the voltage sensors of the similar voltage-gated calcium channel Cav1.1.

T1313M), in the outermost arginine of the voltage sensor in domain IV (R1448H/C/S/P), in intracellular S4-S5 loops of domain III or IV (e.g. F1473S), or in the C-terminus (F1705I) (37). During cooling to 27°C in vitro, paramyotonia muscle fibers slowly depolarize from −85 to about −45 mV, whereas normal muscle fibers depolarize by not more than 5 mV. The depolarization is associated with a long-lasting burst of action potentials, which ends when the membrane potential approximates values of −50 mV (2,41). At this voltage, most sodium channels are inactivated and therefore the muscle fibers become inexcitable and paralyzed. Functional expression of mutant channels revealed slowed fast inactivation and accelerated recovery from the inactivated state and an uncoupling of fast inactivation from activation (5,42). As also slow sodium channel inactivation should be incomplete to maintain depolarization-induced paralysis (43), several groups examined the effects of temperature on slow inactivation of the mutant channels (44–46). The results were not uniform and were difficult to interpret since entry into slow inactivation was already changed by the strikingly slowed fast inactivation. Bouts of long-lasting weakness in paramyotonia can be explained with an ongoing membrane depolarization in the majority of muscle fibers (i.e. a preference of fibers to stay in the P2 state).

**129.4.2.4 Epidemiology.** Paramyotonia is considered an extremely rare disorder, although little epidemiological work has been done. Prevalence is generally higher in Europe-derived populations and lower among Asians. Epidemiological estimates have been provided for the German population. Here, it was estimated that the prevalence is between 1:350,000 and 1:180,000 (47,48). It should be noted, however, that paramyotonia patients are not uniformly distributed across Germany. Many affected families stem from the Ravensberg area in northwest Germany, where a founder effect seems to be responsible for most cases (47,48). The prevalence in that area is estimated at 1:6000.

### 129.4.3 Hyperkalemic, Normokalemic and Hypokalemic Periodic Paralysis

Although in all the periodic paralysis—with the exception of the Andersen–Tawil syndrome (see later)—genes are mutated that encode channels conducting ions other than potassium, the level of serum potassium plays a decisive role on the symptoms, namely, by triggering attacks in the hyperkalemic and normokalemic forms and relieving paralysis in the hypokalemic form (Table 129-1, Figure 129-3). The situation with glucose is similar, because, in combination with insulin, it shifts potassium from the extracellular to the intracellular space and thus may likewise have triggering or therapeutic effects. The same is true for cortisone and drugs that modify the serum potassium level. In contrast, bodily and psychic stress, cold, infections, vaccinations,

operations and drugs always act adversely in all forms of channelopathies. This is even true for the myotonias except that with chloride myotonia cold does not objectively aggravate muscle stiffness, although patients subjectively report worsening. Muscle biopsy is indicated only if molecular genetics does not provide the diagnosis or when there is reasonable suspicion of additional neurogenic or inflammatory processes. Because of possible dangerous situations of hypoglycemia or hypokalemia, diagnostic tests using glucose/insulin loading should be performed only in exceptional cases. Stand-by anesthesia is required.

**129.4.3.1 Clinical Symptoms.** The typical symptom of the periodic paralysis is the experience of episodes of localized or generalized flaccid paralysis that may last for from a few minutes to several days. Respiratory and vocal muscles may be affected. Muscle reflexes might be reduced during an episode. At increased age of the patients, a permanent weakness may additionally develop and result in muscular dystrophy. Hyperkalemic, normokalemic and hypokalemic periodic paralysis are distinguished depending on the serum potassium during a full-fledged episode. The diagnosis between these variants is not always easy, as the result of a single measurement of serum potassium may be misleading. Additional information received from the determination of triggers and the duration of an episode as well as from the reaction to the administration of potassium, sodium or glucose may be helpful. Episodes of hyper- and normokalemic, but not of hypokalemic, periodic paralysis may be accompanied by myotonia. Between episodes, myotonia might be detectable only in the EMG, but at the beginning of an episode, myotonia may be present (49).

The symptoms set in during childhood or youth and only rarely during early adulthood. Frequency and severity of the paralytic episodes decrease from 50 years of age onward, but about 50% of cases then suffer from a chronic progressive muscular weakness with increased CK values, myopathic EMG changes, and histological alterations similar to a vacuolar myopathy or a limb girdle dystrophy. Cases with progressive atrophies have also been described (50). Females with incomplete penetrance for the paralytic attacks may well present with such a myopathy at a later age. In addition to the prevailing medical problems there are also psychosocial and judicial questions that arise during the course of these diseases (occupational suitability, military service, degree of disability, and possibility of therapy). Therefore, advocacy groups, social services, psychotherapists and paramedical services may be of essential help.

**129.4.3.2 Clinical Neurophysiology and Magnetic Resonance Imaging (MRI).** The dyskalemic periodic paralysis show a late decrement under repetitive nerve stimulation. To decide for the appropriate therapy it does not suffice to clarify the form of dyskalemia, one should also search for ictal or interictal edema and for dystrophy using MRI (6,51). The ischiocrural

musculature is particularly likely to be affected by fatty degeneration (52).

**129.4.3.3 Pathogenesis.** Dominant mutations in the gene encoding the muscular voltage-dependent sodium channel Nav1.4 are responsible for hyperkalemic periodic paralysis (53,54) (Figure 129-3). Hypokalemic periodic paralysis is caused by mutations in the protein segments containing the voltage sensors in either of two very homolog muscular ion channels: the sodium channel NaV1.4 and the L-type calcium channel CaV1.1 (encoded by *CACNA1S*) (55–57). In either channel, the mutations generate additional pores in the voltage sensor segments (58). These pores conduct aberrant sodium currents that induce the P2 state in the affected fibers (6). Determination of the specific mutant allows one to predict the minima of serum potassium levels adopted by a particular patient. These minima determine the severity of future paralytic attacks and of secondary cardiac disturbances. They are also responsible for the course of the progressive myopathy.

If the muscle fibers stay in the P2 state for a very long time (54), sodium ions will accumulate in the intracellular space, and by virtue of osmotic forces, this will be followed by accumulation of intracellular water (6). This disequilibrium plus the electrical inexcitability lead to a progressive myopathy that may develop vacuoles or may histologically look like a dystrophy.

**129.4.3.4 Epidemiology.** The periodic paralyses are rare diseases with dominant inheritance. The prevalence of all forms taken together is about 1:50,000. The hyperkalemic form is transmitted with full penetrance, a male to female ratio of 1:1, and a prevalence of 1:200,000 (25). Patients without interictal myotonia are much more prone to develop progressive myopathy and permanent weakness than individuals with myotonia. This is obvious with individuals having the most common T704M mutation: about half of them show myotonia in the EMG and they are the ones who do not develop permanent myopathy. The second most frequent mutation, M1592V, is always associated with myotonia in the EMG, and patients have never been reported to suffer from permanent myopathy.

The most frequent is the hypokalemic form with a prevalence of 1:100,000. It is transmitted with reduced penetrance in women (the male to female ratio is 3 or 4:1). The most common mutations are the Cav1.1 substitutions R528H and R1239H, which both lead to progressive myopathy.

The term normokalemic periodic paralysis was originally given to a variant described in the 1960s. The disorder resembled the hyperkalemic form in many aspects; the only real differences were the lack of increase in the concentration of serum potassium even during serious attacks, and the lack of a beneficial effect of glucose administration. The existence as a nosologic entity was questioned because of the potassium sensitivity of the patients and the identification of the most frequent

hyperkalemic periodic paralysis mutations T704M or M1592V in such families including the original family.

Recently, a potassium-sensitive type of periodic paralysis with normokalemia and episodes of weakness reminiscent of those in both hyperkalemic (initiation of an attack by potassium) and hypokalemic forms (duration of attacks) was reported (59). This phenotype, also named normokalemic periodic paralysis, is caused by *SCN4A* mutations at deeper locations of the voltage sensor of domain II at codon 675 (Figure 129-3). Functionally, R675 mutations generate a leak current with a reversed voltage dependence compared to mutations causing HypoPP-2 since this site is exposed to the extracellular space at stronger depolarizations. Future studies will show whether normokalemic periodic paralysis is a separate clinical entity. The diagnostics are as described for the two more common forms of the disease.

#### 129.4.4 Thyrotoxic Hypokalemic Periodic Paralysis

Thyrotoxic hypokalemic periodic paralysis resembles familial hypokalemic periodic paralysis with respect to changes in serum and urinary electrolytes during attacks and in its response to glucose, insulin, and rest after exertion. It differs from familial hypokalemic periodic paralysis as it occurs only in the course of hyperthyreosis, even though the latter does not need to be clinically obvious. While Graves' disease (hyperthyroidism only) shows a 5:1 female to male predominance with a prevalence of 2% in the general population, this ratio is about 1:6 in thyrotoxic hypokalemic periodic paralysis, at least in Asian patients. Statistically, the incidence of periodic paralysis in Asian men with Graves' disease has been estimated at between 13 and 24% (25). More than 75% of the cases occur in Asians, suggesting a predisposing racial factor (Chinese, Japanese, Korean, and Vietnamese). The attacks occur much more frequently in summer than in winter. A geographical component is not likely, because Chinese or Japanese immigrants in North or South America have the same disease frequency as in their country of origin. Reports of cases in Caucasians and Blacks indicate that the disease rarely occurs in non-Asians (60).

The onset of disease is usually after the age of 20 years. Forty-five percent of the patients develop the syndrome in the third decade, another 35% in the fourth, and the rest in the fifth decade of life. The thyrotoxicosis precedes or appears simultaneously with the periodic paralysis in more than 80% of the patients (61), but the thyrotoxic signs are relatively mild at the time of the initial attack (no palpitations, goiter, or exophthalmus). Typical are sudden paralytic attacks of proximal limb muscles after strenuous exercise or at rest following high-carbohydrate meals in the evening or during the night, and hypokalemia during the attacks. The serum potassium falls to levels below 3.5 mM in 80% of the patients. In some patients

it may be as low as 1.2 mM and cause life-threatening arrhythmias or sinoatrial block. As the hypokalemia is the result of an insulin-induced shift of potassium from the extracellular to the intracellular space of the muscles, potassium is released from the muscle at the end of an attack to cause rebound hyperkalemia. During an attack, both the arrhythmia and the acute paralytic attack are relieved by administration of potassium. The paralytic attacks cease when the euthyroid state is restored, but recurrence of the hyperthyroid state causes recurrence of the paralytic attacks.

*KCNJ18*, a gene encoding the inwardly rectifying potassium channel Kir2.6, was mutated in the four who were from Singapore of thirty unrelated Chinese patients (62) (Table 129-1). Kir2.6 is transcriptionally regulated by thyroid hormone.

### 129.4.5 Andersen-Tawil Syndrome

This is a very rare disease, characterized not only by episodes of paralysis but also by life-threatening ventricular arrhythmias. During paralysis, the serum potassium level may be increased, normal or reduced (63). Accordingly, the response to oral potassium is unpredictable. The ECG should be monitored at rest and also in long-term observations. Some of these patients show skeletal abnormalities of the face, hands and/or feet. Mutations of the Kir2.1 potassium channel, an inward rectifier expressed in skeletal and cardiac muscle, are causative of the disorder (64) (Table 129-1, Figure 129-4). Kir2.1 channels are essential for maintaining the highly negative resting membrane potential of muscle fibers and accelerating the repolarization phase of the cardiac action potential. The mutations mediate loss of channel function by haploinsufficiency or by dominant-negative effects on the wild-type allele and may lead to long-lasting depolarization and membrane inexcitability. The prevalence is estimated to be <1:1,000,000.

### 129.4.6 Differential Diagnosis and Therapy of the Myotonias and Periodic Paralysis

**129.4.6.1 Differential Diagnoses.** When diagnosing myotonia patients one should always think of the myotonic dystrophies (DM), in particular if they have cataracts as in DM1 or atypical breast pain as in DM2. Patients having events of periodic paralysis may suffer from dyskalemia (e.g. accompanying Conn's or Addison's syndrome). In contrast to genuine periodic paralysis these conditions are accompanied by long-term pathologic alterations of muscle force and serum potassium. Of course, a so far compensated state can be decompensated by an acute additional change in serum potassium, and thus lead to an episode of paralysis.

**129.4.6.2 General Anesthesia.** Myotonia patients deserve special attention before and during narcosis. In particular, if the myotonia is not readily recognizable as

○ Andersen's syndrome — Deletion

**FIGURE 129-4** Membrane topology model of the inward rectifying Kir2.1 potassium channel of skeletal and cardiac muscle. Kir2.1 is a voltage-independent potassium channel encoded by *KCNJ2*. The functional channel is a homotetrameric protein. Mutations in the channel cause Andersen's syndrome.

in hyperkalemic periodic paralysis and myotonia fluctuans, the use of potassium and other depolarizing agents such as suxamethonium and cholinesterase inhibitors can provoke the myotonic reaction and thus compromise intubation and respiration. This can induce life-threatening incidents (65). Moreover, stress caused by the operation may lead to hypokalemia and may trigger a paralytic attack in patients with hypokalemic periodic paralysis. Development of hypokalemia during narcosis may evoke local generalized muscle weakness in all forms of periodic paralysis. Therefore, measures to retain body temperature should always obviate hypothermia of the patient during the operation.

**129.4.6.3 Therapy.** Therapeutic studies of the periodic paralyses have so far only been performed with dichlorophenamide (available only in Italy as Fenamide®) (66). Systematic studies for the therapy of the myotonias and periodic paralyses do not exist and, therefore, recommendations are not supported by evidence-based data (67–69).

In cases of benign myotonia no medication is required because patients learn to handle their disorder. Patients having a sodium channel myotonia should avoid strenuous ventures like hikes in the mountains. In cases of severe myotonia as in myotonia permanens or in cases of Becker myotonia, where medication seems appropriate, antiarrhythmic drugs have the best effect. By virtue of their “use-dependent” action they block in essence the pathologic after-activity without affecting the excitability per se. Their therapeutic window is, however, narrow. They not only affect the sodium channels but also improve chloride channel myotonia, although not so effectively as they do with sodium channel myotonia. For a long time the Ib-antiarrhythmic drug mexiletine was the drug of choice (70,71), but recently it has been taken off the market (with the exception of Japan) because of low cost-effectiveness. As alternatives, the Ic-antiarrhythmic

drugs flecainide and propafenone are available (72) (Table 129-1). Electro- and echocardiogram should be recorded before administration to avoid a heart bundle block. During use of one of the above antiarrhythmics, patients having heart insufficiency or arrhythmias should have no prolongation of the QRS-complex by more than 20% and the QT time should be no longer than 500 ms. The absolute QTc time should remain stable. Regular cardiologic controls are recommended with all patients. The control of serum potassium values and the monitoring of potential cardiac or central nervous side effects, as well as the avoidance of dehydration will permit a lifelong treatment, even with beginning in childhood. In the case of cardiac disturbances one may sidestep to the well-compatible drug lamotrigine. Carbamazepine or phenytoin should not be used because of their low anti-myotonic action.

With paramyotonia patients, a short-term therapy, e.g. for 2–3 days before the exposure to cold, is preferable to a long-term treatment. The same is true for sodium channel myotonia and extreme bodily stress. Patients with hyperkalemic periodic paralysis should avoid strong bodily stress and should have frequent and smaller meals. They should also avoid potassium-rich food (dried fruit, bananas, apricots, cauliflower, leguminous plants, etc.). For prophylaxis, medication with thiazide diuretics or carbonic anhydrase inhibitors is recommended (73). Both types of drugs stimulate the excretion of potassium, the latter ones, however, only to a small extent so that they can also be used for the hypokalemic form (see later). Beta-sympathomimetic drugs like salbutamol, when taken at the onset of an episode, may ease the symptom rather quickly. In addition, the simultaneous application of glucose and insulin may lower serum potassium rather quickly; in exceptional situations also a slow intravenous injection of calcium gluconate may be appropriate.

With normokalemic periodic paralysis patients, avoidance of dyskalemia and medication with carbonic anhydrase inhibitors are a suitable prophylaxis against paralytic episodes. Patients with hypokalemic periodic paralysis should avoid foods rich in carbohydrates and strong bodily work. They should eat foods rich in potassium (see earlier) and low in sodium. To avoid paralytic episodes, medication with carbonic anhydrase inhibitors like acetazolamide and dichlorphenamide and/or the aldosterone antagonist eplerenone is recommended. Potassium saving diuretics like triamterene or amiloride would also be suitable, but in certain countries they are available only in combination with potassium-excreting diuretics; this, of course, counteracts their effect. Mono-substances can be imported from abroad. The dose of the drugs should be slowly increased (e.g. eplerenone should start with 12.5 mg/day and be increased by 12.5 mg/day in the second week, etc.). A combination of carbonic anhydrase inhibitors, potassium-sparing diuretics and potassium, each at low dosage, may reduce the side

effects of the drugs. With this combination, the possibility of hyperkalemia with muscular weakness and cardiac arrhythmias exists, which persists until the hyperkalemia is reversed. The danger of this possibility to happen is, however, much lower than feared by many physicians, because most of the patients present even in the interval with serum potassium values at the lower norm. In fact, it turns out to be rather difficult to raise their serum potassium level to a persisting 4.8–5.2 mM, values that would suffice to let them experience less muscle weakness, less muscle pain and a reduced number of paralytic episodes.

In some patients, carbonic anhydrase inhibitors have an opposite effect: for reasons unknown they lead to an increase in the number and severity of paralytic attacks (74). In these cases aldosterone antagonists and potassium-sparing diuretics are helpful (6). At least in an acute episode potassium should be administered. The mentioned drugs are also effective in antagonizing the lasting muscle weakness, provided muscle tissue is still preserved (6). Since it has been shown that potassium may repolarize depolarized muscle fibers of patients with hypokalemic periodic paralysis, potassium should be given not only during a paralytic episode but also as a prophylactic measure. This may sound paradoxical, but often it works. Best suited are slow-retard potassium tablets (6).

A thyrotoxic hypokalemic periodic paralysis is best cured by treating the hyperthyreosis. In an acute case potassium and carbonic anhydrase inhibitors may be used (25). Some experts also advocate beta-blockers.

In Andersen-Tawil syndrome carbonic anhydrase inhibitors can be used as prophylactic means against paralytic attacks. Extrasystoles should not be treated at any cost; often the arrhythmias disappear with tachycardia, as with moderate bodily stress or fever. A treatment with blockers of the sodium or calcium channels or with beta-blockers is common but often not effective. Earlier investigators reported imipramine as useful. Amiodarone should be given only in severe cases because of its substantial side effects. For the long-QT syndrome this drug is even contraindicated (75). In cases of rhythmogenic syncope a pacemaker or a combined pacemaker/defibrillator may be indicated. All drugs that prolong the QT time are strongly contraindicated.

## 129.5 HEREDITARY CHANNELOPATHIES OF EXCITATION-CONTRACTION COUPLING

MH, central core myopathy and multiminicore myopathy are allelic diseases; they are all caused by mutations in the same gene *RYR1* (76,77). Most *RYR1* mutations result in a dominant predisposition to MH, which may occur as a life-threatening complication during an inhalation narcosis. Central core myopathy and multiminicore myopathy are diseases that can also be generated by mutations in other genes. For safety reasons, with

general anesthetics in patients with any kind of central core or multiminicore myopathy it is always assumed that there is an increased risk of a developing MH (78).

### 129.5.1 Malignant Hyperthermia (MH) and Malignant Hyperthermia Susceptibility (MHS)

MH is a dangerous condition even 50 years after its first description. Its dangerousness is evident from the fact that all over the world institutions of anesthesiology hold the antidote dantrolene in stock. Frequency of clinical crises, as well as lethality, have been substantially lowered over the past years by prevention, identification of susceptible persons, education of affected families and instruction of personnel. These measures have substantially contributed to the safety of patients in the area of anesthesiology.

The frequency of the genetic disposition to MH is estimated at 1:3000 in Caucasians. The clinical incidence is higher in children than in adults and estimated to be 1:50,000 or 1:100,000 for general anesthetics. These estimates, however, are based on clinical data collected at times when the classical trigger substances halothane and succinylcholine were frequently used in combination and at high doses. Nowadays, events of clinical crises must be assumed to occur at a much lower frequency. With the exception of NO and xenon, all volatile anesthetics and depolarizing muscle relaxants (the latter perhaps only in combination with the further) can elicit an MH crisis. Extreme bodily stress, a hot environment and infections may also trigger an “awake episode.” On the other hand, there are now a multitude of anesthetic drugs at hand for which safe applicability to persons susceptible to MH (MHS) has been proven. This permits the application of regional and general anesthetics also with MHS persons.

The clinical symptoms of an MH crisis (hypermetabolism, tachycardia, muscle spasms, increase in respiratory CO<sub>2</sub>, and rise in body temperature) are all based on an excessive release of Ca<sup>2+</sup> from the sarcoplasmic reticulum (SR). In about 50% of the families this excess is caused by a mutation in *RYR1*, the gene encoding the muscular Ca<sup>2+</sup> release channel, also called ryanodine receptor. In a few families, MH susceptibility is caused by mutations in *CACN1A5* (79), the gene encoding the muscular L-type calcium channel (i.e. the same channel that causes hypokalemic periodic paralysis when mutations alter its voltage sensors).

The diagnosis of MH susceptibility is still performed using the invasive in vitro contracture test (IVCT). This test is a functional, standardized procedure (80) in which the force developed in a contracture of the tested person's muscle biopsy is taken as an indirect marker for the sensitivity to contracture-triggering substances such as caffeine and halothane. In contrast to the IVCT test protocols primarily aimed at determining the clinical risk of

anesthesia-related events, diagnostic testing in Japan is performed by a functional test based on the quantification of calcium-induced calcium release (CICR) in saponized muscle fibers (81). The precision of this method and correlation to the other protocols is unknown. In addition to functional tests, a histological investigation may give evidence for central core myopathy or multiminicore myopathy, conditions that are frequently associated with MH susceptibility.

An a priori genetic investigation of a subject with potentially increased risk of MHS is costly because the *RYR1* gene consists of 106 exons. Usually MH susceptibility is first tested using IVCT and in the positive case the search for the mutation begins. For consanguineous relations of a proband with a causative mutation, a mere genetic investigation is sufficient. The number of mutations determined with respect to MHS has over the years increased to more than 100 (Figure 129-5). However, in only 30 mutations has a causative connection been established (10,82–84).

A person that has passed several general anesthetics without problems may not necessarily be taken to be MHS-negative for sure, because the likelihood of an MH crisis occurring during general anesthesia is only 1:5. It should be mentioned that MHS-positive persons should not undergo extreme bodily stress (marathon, triathlon, and competitive sports) or exposure to extremely high environmental temperature. Excessive alcohol consumption and abuse of drugs (ecstasy, amphetamines, or cocaine) may also elicit MH (85).

### 129.5.2 Central Core Myopathy

Patients with central core myopathy typically present already at birth with hypotrophy and hypotonia of the musculature (floppy infant) and later show delayed motor development. Quite often they have a congenital subluxation of the hip and later develop scoliosis. Weakness of the pelvic and humeral musculature is conspicuous. Usually there is neither restriction of the bulbar and respiratory muscles nor an external ophthalmoplegia. Most patients become stronger as they grow up and can walk independently. According to personal observations bodily endurance training seems to have positive effects. Only a minority of the children show a progressive course. Differential diagnosis to nemaline myopathy and multiminicore myopathy is sometimes difficult (86).

Central core myopathy is in most cases inherited as an autosomal dominant trait with alternating penetrance. Many family members of a patient are only diagnosed when they undergo genetic investigation. Since both central core myopathy and susceptibility to MH are caused by mutations in *RYR1*, it is assumed that persons having such a mutation are in any case susceptible to MH, no matter whether they show the disease or not (although exceptions to this rule have been reported). These exceptions pertain to mutations

## Ryanodine receptor RYR1

**FIGURE 129-5** The skeletal muscle ryanodine receptor (RyR1) forms a homotetrameric protein complex that is situated in the sarcoplasmic reticulum (SR) membrane and functions as calcium release channel. The cytosolic part, the “foot”, bridges the gap between the transverse tubular system and the SR. It contains binding sites for various activating ligands such as  $\text{Ca}^{2+}$  (in micromoles), ATP, calmodulin, caffeine and ryanodine (in nanomoles), and inactivating ligands such as dantrolene,  $\text{Ca}^{2+}$  ( $>10\mu\text{M}$ ), ryanodine ( $>100\mu\text{M}$ ), and  $\text{Mg}^{2+}$  (in millimoles). The transmembrane segments are numbered M3–M10. The first two cylinders with dashed lines indicate the tentative nature of the composition of the first predicted helical hairpin loop (M3–M4 or M4a–M4b). The long M7 sequence is designated as M7a and M7b. The proposed selectivity filter between M8 and M10 is designated as M9 even though it is clearly not a transmembrane sequence. Mutations causing susceptibility to malignant hyperthermia and/or central core disease are indicated.

in the C-terminal region of *RYR1*, which, in contrast to all other mutations, do not result in an increased, but a reduced,  $\text{Ca}^{2+}$  release. The reduced  $\text{Ca}^{2+}$  release could explain the muscle weakness. Mutations that lead to an increased open probability of the  $\text{Ca}^{2+}$  channel (“leaky channels”) could also generate the weakness by depleting the sarcoplasmic  $\text{Ca}^{2+}$  stores.

Serum CK is usually normal or only slightly increased. A conspicuous feature of the muscle biopsy is the dominance of type 1 fibers. NADH staining shows the characteristic centrally localized cores by the absence of an intermyofibrillar oxidative network. Longitudinal sections show that a core usually extends from one end to the other of type 1 fibers.

### 129.5.3 Multiminicore Myopathy

It is a recessively inherited congenital myopathy with genetic heterogeneity (87). The classic form of the disease usually leads to severe scoliosis. The affected muscles show an axial distribution, i.e. respiratory, bulbar and extraocular muscles are often struck. This form of the disease is caused by mutations in the gene *SEPN1*, encoding selenoprotein N, a protein that seems necessary for the release of  $\text{Ca}^{2+}$  from the SR.

Another form of multiminicore myopathy is caused by mutations in the *RYR1* gene (88). It is less severe, and scoliosis is little pronounced if at all. Patients show generalized muscle weakness with accentuation of the pelvic girdle and the hand muscles. Amyotrophy and hyperextensibility of the joints prevail (89). As with central core myopathy the course of the disease is rather benign and rarely progressive. Histology is also similar except that the cores do not extend over the whole fiber length and have fuzzy ends. In some patients having a core myopathy, mutations were found in *ACTA1*, a gene coding for alpha actin.

Monoallelic expression is the explanation for the question why the mode of inheritance of some of the core myopathies is difficult to explain (89,90). Several features of the silencing of the wild-type allele show characteristics of genomic imprinting; first, the sex of the nontransmitting parent is regularly female; second, the monoallelic silencing follows a tissue-specific pattern; and last, control fetuses generally show *RYR1* silencing in 10% of cases with tissue-specific expression (91).

## 129.6 CRITICAL POINTS IN FUNCTIONAL AND GENETIC STUDIES

### 129.6.1 In Vitro Functional Studies of Channel Mutants

Functional expression of mutations has contributed to the understanding of the molecular pathogenesis of almost all muscle channelopathies. However, there are undeniable problems of interpreting changes in function brought about by mutants in in vitro expression systems. The overexpression of introduced DNA in a heterologous cell system may lead to a nonphysiological localization of the encoded protein. This can lead to a false conclusion regarding channel significance. Second, the cells chosen for functional expression may have endogenous channel subunits that can potentially interact with or be upregulated by the introduced DNA. These can generate currents, which may be falsely assumed to appear because of the introduced DNA (compare (92) with (93) and (94)). Third, heterologous expression systems may secondarily modify the channels chemically, which may lead to misinterpretation of the functional significance of the channel subunits. An example of such a possibility is the skeletal muscle sodium channel Nav1.4, which exhibits more rapid

inactivation kinetics when expressed in human embryonic cell lines than in *Xenopus* oocytes. Originally, this finding was attributed to the lack of expression of the accessory  $\beta$  subunit in the oocytes; however, the rapid kinetics of the channel were also found when expressed in cells without endogenous  $\beta$  subunits. Therefore, post-translational modifications and association of sodium channels with other membrane proteins such as cytoskeletal components are now considered responsible for the differences in kinetics (5).

In short, the function of ion channels is highly dependent on the expression system used. The functional significance implied by these experiments may not necessarily be valid for the physiological situation in vivo. Moreover, the finding of a functional change may not necessarily indicate a mutation, but could instead be brought about by a polymorphism. In spite of inherent difficulties in the publication of such findings, several of these “functional polymorphisms” have been described. For example, S906T in Nav1.4 was found to segregate perfectly with periodic paralysis in several large pedigrees and was alleged to alter entry into and recovery from slow-channel inactivation. However, S906T occurs in 5% of the population without association with any disease (95). In the periodic paralysis families mentioned, it turned out that S906T happened to be linked to a much later identified causative change.

### 129.6.2 Genetic Screening of Control Populations

Owing to the shortcomings of the interpretation of functional studies, the genetic screening of large and adequately matched control populations for absence of the putative mutations is important to prove disease causality. Two reports have proposed the typing of 150–200 controls (300–400 chromosomes) for putative mutations with a prevalence of 1% by power analysis (96,97). A more general algorithm that recommends exclusion of the putative mutation in ethnically matched control chromosomes has recently been proposed (98). According to it, for a proposed maximally tolerable error of 1% and a mutation present on 1% of the tested patient chromosomes, at least 460 control chromosomes (230 control individuals; Figure 129-6) should be tested.

Therefore, the common laboratory practice to exclude a novel mutation in approximately 100 healthy controls is insufficient. An example for spurious conclusions is an R83H substitution in a potassium channel  $\beta$  subunit, MiRP2, suggested to cause dyskalemic periodic paralysis because it showed a loss of function in vitro and was found in two of 100 of such patients but in none of 120 unaffected controls (99). In later studies, the substitution was identified not only in one of 104 and one of 138 patients but also in eight of 506 and three of 321 controls (49,100). Taken together, the substitution is present in 1.17% of patients and in 1.16% of healthy controls, which does not support disease

**FIGURE 129-6** Number of required control chromosomes as proposed by a statistical equation to minimize the error. Let the prevalence of a mutation in a patient's chromosomes be  $p_1$  and the prevalence in control chromosomes be  $p_0$ ; then, the probability of an arbitrary control chromosome not to carry the mutation is  $(1 - p_0)$ . Because the world control population is large, the probability  $P$  of arbitrarily choosing  $n$  chromosomes thereof without the mutation may be approximated by  $P = (1 - p_0)^n$ . The null hypothesis would be that the mutation frequency is equal in patient and control chromosomes, i.e.  $p_0 = p_1$  and  $P = (1 - p_1)^n$ . The number of control chromosomes to be tested can be calculated by resolving the equation for the number  $n = \ln(P)/\ln(1 - p_1)$ . By setting an error probability  $P$  of 1%, the number of required control chromosomes is  $n = -4.6/\ln(1 - p_1)$  and  $n = 460$  for the example of  $p_1 = 1\%$ . The curve demonstrates that 100 control individuals (200 chromosomes) would be adequate for a  $p_1$  of 2.5%, a prevalence that is much higher than the most frequent monogenic disorder.

causality. Even though the difference between defining a putative mutation as being truly disease causing or as being a functional polymorphism may seem only marginal on a scientific level, this difference in definition has drastic consequences for an affected carrier whose diagnosis is made or confirmed by the finding and who is being medically treated. This problem will increasingly need to be addressed in future studies when the number of known mutations and putatively associated phenotypes continues to increase.

### Biographies

**Frank Lehmann-Horn** has a Master's degree in mechanical engineering and is a Medical Doctor specializing in neurology and physiology. In 1986, he received the degree of Dr habil in neurology at the Technical University in Munich. Next to his scientific work and his teaching responsibilities, he takes care of many patients with myotonias, periodic paralyses, episodic ataxia, migraine and individuals susceptible to malignant hyperthermia. In 1992, Dr Lehmann-Horn became Head of the Institute of Applied Physiology at Ulm University. In 2005, Dr Lehmann-Horn was awarded the Dr honoris causa (Dr.h.c.) of the University of Debrecen in Hungary for his scientific collaborations on muscle excitation–contraction coupling and the coordination of two European networks sponsored by the European Union. In 2008, he was elected for the Endowed Research Senior Professor for Neurosciences of the Hertie-Foundation. In 2009, he became a member of the Heidelberg Academy of Sciences and was awarded the Art of Listening Award from the Genetic Alliance, Washington, DC. In 2010, as Hertie Senior Research Professor of Neurosciences, he became Head of the Division of Neurophysiology of Ulm University. Currently, he is Chairman of the Ulm Muscle Centre.

**Reinhardt Rüdel**, born in 1937, studied physics and medicine at the Universities of Erlangen, Vienna and Heidelberg. In 1965, he received a PhD in physics, and in 1970, the degree of Dr habil in physiology, both at the University of Heidelberg. His main academic teachers were Wolfgang Trautwein and Josef Dudel at Heidelberg, Sir Andrew Huxley at London and John R. Blinks at the Mayo Clinic in Rochester, MN. In 1971, he became interested in studying muscle diseases characterized by disturbed excitation, first with Erich Kuhn in rat model myotonia, and later with Kenneth Ricker and Frank Lehmann-Horn in excised intercostal muscle bundles from patients. From 1972 to 1979, he was professor of physiology at the Technical University of Munich; from 1979 to 2004 he was chairman and director of the Institute of General Physiology at the University of Ulm. There, he founded the Neuromuscular Center in 1993, always continuing with research into neuromuscular disorders. Being a wheelchair-bound muscle patient himself, he was very active in advocacy organizations for patients with muscle disorders serving as president of the German MDA from 1986 to 1992 and as president of the European MDA from 1987 to 1993. He was president of the VIIth International Congress on Neuromuscular Disorders in Munich and one of the three founders of the European Neuromuscular Centre (ENMC) at Baarn/the Netherlands. From 2000 to 2001 he was president of the German Physiological Society. At present, he is vice president of the Gaetano Conte Academy for the study of striated muscle at Naples/Italy.

**Karin Jurkat-Rott** is a Medical Doctor specialized in Physiology and working as deputy chair in the Division of Neurophysiology, Ulm University. In 2001, she received the degree of Dr habil in physiology at Ulm University. She is the scientific secretary of both the Ulm Muscle Center and the Ulm Center on Rare Diseases. Her main goal is to elucidate the pathogenesis of diseases that are caused by pathologically altered ion channels known as channelopathies. Examples are myotonia, periodic paralysis, ataxia and migraine. By genetic, functional and patient studies, she is developing models for pathogenesis and strategies for therapy. In addition, she is interested in various aspects of ion channels, e.g. their coding genes, the splicing of the RNA, the function of the channel proteins, and their modulation by exo- and endogenous ligands and toxins.

## Myotonic Dystrophies

Chris Turner

MRC Centre for Neuromuscular Disease, National Hospital for Neurology and Neurosurgery,  
London, UK

This article is a revision of the previous edition article by Tetsuo Ashizawa and Peter S Harper, volume 3, pp 3047–3071,  
© 2001, Elsevier Ltd.

### 130.1 INTRODUCTION

Myotonic dystrophy (dystrophia myotonica 1, Steinert's disease; OMIM 160900) is an autosomal dominant disorder, clinically characterized by myotonia, dystrophic muscle degeneration, lens opacities, and variably associated other multisystemic phenotypes. The mutation responsible for the disease is an expansion of unstable CTG trinucleotide repeats in the 3' untranslated region (UTR) of the dystrophia myotonica protein kinase (*DMPK*) gene on chromosome 19q13.3. The identification of this mutation led to the recognition of autosomal dominant families whose clinical manifestations closely resemble this disease, but whose *DMPK* gene shows no CTG repeat expansion. The disease of these families was initially named proximal myotonic myopathy (PROMM; OMIM 602668) because of predominantly proximal distribution of muscle weakness and atrophy. The genetic mutation found in most of these families is an expansion of an intronic CCTG repeats in the zinc finger 9 (*ZNF9*) gene on chromosome 3q13.3–q24. The characteristics of this mutation are strikingly similar to that of myotonic dystrophy; both are large expansions of microsatellite repeats that are transcribed into RNA with repeated CUG motifs but not translated into the respective protein products. The pathogenic mechanisms of these two diseases have been speculated to be similar and predicted to be mediated by a “*trans*-dominant gain-of-function” involving repeat-containing RNA transcripts. At the Third International Myotonic Dystrophy Consortium meeting (1) the nomenclature of the genetic loci of these disorders was changed to *myotonic dystrophy type 1* (DM1) for myotonic dystrophy and *myotonic dystrophy type 2* (DM2) for PROMM. In 2003, the 115th European Neuromuscular Center (ENMC) workshop adopted the term myotonic dystrophy type 2 (DM2) as the clinical nomenclature for the entire progressive myotonic multiorgan disorders linked to the DM2 locus (Table 130-1) (2).

DM1 is the most common muscular dystrophy of adult life and presents with a variety of clinical challenges to all those involved with affected patients and

their families. The wide range of severities, age at onset and the multi-system involvement requires that a corresponding variety of specialists often need to be involved in the management of DM1 patients. Clinical geneticists encounter DM1 as a frequent cause for referral in relation to genetic counseling, presymptomatic detection, and prenatal diagnosis. As a result of their involvement with the whole family, clinical geneticists may be the first to make the diagnosis, especially in affected individuals at the extremes of life, when the disorder is often not recognized until it can be placed in the context of the family.

In contrast, DM2 presents with a milder, although potentially disabling, phenotype. The clinical features and the genetic mutation of DM2 resemble those of DM1, but the pattern of instability of the genetic mutation and of the genotype–phenotype correlation is very different between DM1 and DM2. Clinical geneticists may deal with these differences when genetic testing shows no DM1 mutation in patients suspected to have DM1.

The identification of the molecular basis of the mutation has made a significant impact in the management of patients with DM1 and DM2. This is true not only for the genetic aspects of the diseases, but increasingly for our understanding of the clinical variability. The cell biology and possible molecular processes involved in the pathogenesis of the disorder have proved to be complex and have enlightened our understanding of a broader group of diseases associated with gain-of-function mutations involving RNA. A more detailed account of the various clinical aspects of DM1 might be found in the recent edition of the monograph of Harper (3) and review by Turner and Hilton-Jones (4).

### 130.2 CLINICAL FEATURES

#### 130.2.1 Clinical Features of Myotonic Dystrophy Type 1

**130.2.1.1 Clinical Features and Differential Diagnosis of Myotonic Dystrophy Type 1.** DM1 was first recognized as a specific clinical entity in the

**TABLE 130-1 Nomenclature of Myotonic Dystrophies**

Disorder	OMIM#	Alternative Names	Disease Map Locus	Gene	Location	Mutation
Myotonic dystrophy type 1	#160900	Dystrophia myotonica 1 DM1 Steinert's disease	<i>DM1/19q13.2–q13.3</i>	<i>DMPK</i>	3'UTR	CTG expansion
Myotonic dystrophy type 2	#602668	Proximal myotonic myopathy Dystrophia myotonica 2 Ricker's disease PROMM DM2	<i>DM2/3q13.3–24</i>	<i>ZNF9</i>	Intron 1	CCTG expansion

**TABLE 130-2 Inherited Myotonic Disorders**

Disorder	Inheritance	Basic Defect
Myotonic dystrophy type 1 (DM1)	Autosomal dominant	CTG expansion in <i>DMPK</i> (chr.19)
Myotonic dystrophy type 2 (DM2/PROMM)	Autosomal dominant	CCTG expansion in <i>ZNF9</i> (chr.3)
Myotonia congenita (Thomsen's disease)	Autosomal dominant	Muscle Cl <sup>-</sup> channel ( <i>CLCN1</i> ) (chr.7)
(Becker's Disease)	Autosomal recessive	Muscle Cl <sup>-</sup> channel ( <i>CLCN1</i> ) (chr.7)
Paramyotonia congenita	Autosomal dominant	Muscle Na <sup>+</sup> channel ( <i>SCN4A</i> ) (chr.17)
Sodium channel myotonia	Autosomal dominant	Muscle Na <sup>+</sup> channel ( <i>SCN4A</i> ) (chr.17)
Periodic paralysis (Hyperkalemic)	Autosomal dominant	Muscle Na <sup>+</sup> channel ( <i>SCN4A</i> ) (chr.17)
Chondrodystrophic myotonia (Schwartz–Jampel)	Autosomal recessive	Perlecan ( <i>HSPG2</i> ) defect (chr.1)

descriptions by Steinert (5) and by Batten and Gibb (6), both in 1909. DM1 had previously been confused with the non-dystrophic myotonia, “myotonia congenita” which had been described earlier by Thomsen in his own family (reviewed by Harper (3)). The group of non-dystrophic myotonias is discussed fully in Chapter 129, although it is mentioned later in relation to the differential diagnosis of DM1.

Table 130-2 summarizes the principal inherited myotonic disorders. The multisystemic nature of DM1 was apparent from the earliest studies; Steinert's original paper mentioned testicular atrophy, and by 1912 Greenfield and Curschmann independently recognized that cataracts are part of the clinical picture. In 1918, Fleischer showed that cataracts may be the sole clinical feature and that such individuals may connect apparently separate families with DM1. These observations by Fleischer proved of particular importance, laying the foundation for the concept of “anticipation,” as discussed later (reviewed in Reference (3)).

Although DM1 may present initially to a wide variety of specialists, a neurologist, because of muscle weakness or myotonia, will see many. The distribution of muscle involvement is characteristic, and the combination of myotonia with significant weakness and wasting often permits a confident clinical diagnosis of DM1. The facial muscles, sternomastoids, and distal limb muscles are usually the earliest to be affected, exhibiting a pattern differing from most other neuromuscular disorders, and contrasting with that seen in the other primary muscular dystrophies, as summarized in Table 130-3. Facioscapulothoracic dystrophy, which also shows prominent facial

muscle involvement, has a much greater degree of shoulder girdle weakness, and lacks clinical myotonia. The facial features of DM1 are an important early and visible characteristic (Figures 130-1 and 130-2), and old photographs may be a valuable diagnostic aid.

Myotonia is the delay in relaxation of a muscle following contraction. Myotonia in DM1 is best elicited by asking the patient to grip firmly and to then let go, in order to elicit handgrip myotonia, or by firm percussion of the thenar eminence or the brachioradialis muscle to elicit thumb or wrist myotonia. Percussion of the tongue may show a persistent furrow. Myotonia of other muscles is rarely obvious in DM1. Myotonia may be minimal in cases with advanced wasting and is usually clinically undetectable in young children. Some younger adult patients may present solely with symptoms of handgrip myotonia.

When myotonia is the principal finding, DM1 must be distinguished from other myotonic disorders, in particular myotonia congenita. This is usually straightforward (Table 130-4), especially if other family members show typical features, but the occasional early case of DM1 with little weakness may be difficult to distinguish. The myotonia in DM1 and myotonia congenita usually improves after repetitive exercise of the muscle, which is known as the “warm-up phenomenon,” whereas myotonia in some sodium channelopathies exhibits paradoxical worsening by sustained muscle contraction (paramyotonia). Electromyography (EMG) shows myopathic changes including small-amplitude, short-duration motor units and electrical myotonia. The combination of myopathic changes and myotonia on EMG can help to distinguish between “non-dystrophic” myotonic conditions, such as

**TABLE 130-3 Muscle Involvement in Myotonic Dystrophy and Other Adult Muscular Dystrophies**

<sup>c</sup>Ankle dorsiflexion weakness is common in FSHD.

**FIGURE 130-1** Facial features of myotonic dystrophy. Note particularly the ptosis, facial weakness, and wasting of the jaw and sternomastoid muscles. (From Harper, P. S. *Myotonic dystrophy*. WB Saunders: Philadelphia, 1989, pp 17 (38))

**FIGURE 130-2** Facial features of myotonic dystrophy. Note particularly the ptosis, facial weakness, and wasting of the jaw and sternomastoid muscles. (From Harper, P. S. *Myotonic dystrophy*. WB Saunders: Philadelphia, 1989, pp 17. (38))

myotonia congenita, and “dystrophic” myotonias such as DM1 and 2. Muscle pathology shows a number of characteristic features in the classic adult form of the disease and is usually not needed to be performed to obtain a diagnosis. A confirmed genetic diagnosis based on clinical suspicion is better clinical practice.

In DM2, the distribution of muscle weakness is more proximal and myotonia is less severe. The striking resemblance between DM1 and DM2 warrants special consideration and DM2 is separately described later in the chapter.

**130.2.1.2 Smooth Muscle Involvement in Myotonic Dystrophy Type 1.** Smooth muscle, particularly of the gastrointestinal tract, is prominently involved in DM1 (Table 130-5). A study in Sweden has shown that for many patients gastrointestinal problems are the

most prominent symptom (7). The esophagus may show severely disturbed peristalsis in patients with relatively little weakness, which probably contributes to the aspiration pneumonia frequently seen in older patients, as well as in severely affected infants. Gastric emptying is delayed (8). Colonic involvement is common, and colicky abdominal pain is frequent in affected children, in whom megacolon may occur. Intestinal pseudo-obstruction may occur in both children and adults (9) mimicking a surgical emergency, but the condition normally responds to conservative treatment. Adult patients often have irritable bowel-type symptoms.

**130.2.1.3 Cardiopulmonary Involvement.** Cardiac involvement is an important clinical feature (see Reference (10) for a review; Table 130-6). Sudden death in adults is common and may have been underestimated in

**TABLE 130-4** Adult Clinical Features of Myotonic Dystrophies and Myotonia Congenita

	Myotonia Congenita	Myotonic Dystrophies (DM1 and DM2)
Onset of myotonia	Infancy or early childhood	Late childhood to adult life
Severity of myotonia	Often severe, generalized	Usually mild or moderate
Muscle weakness	Absent or late onset	Variable—mild to severe
Cardiac and smooth muscle	Absent	Common
Cataract	Absent	Diagnostic
Other systemic abnormalities	Absent	Widespread
Inheritance	AR, AD, sporadic	AD with anticipation

DM1, myotonic dystrophy type 1; DM2 myotonic dystrophy type 2. AR/AD autosomal recessive/dominant.

**TABLE 130-5** Gastrointestinal Tract Involvement in Myotonic Dystrophy Type 1\*

Anatomic Structure	Description
Pharynx	Delayed relaxation, retention of bolus, frequent tracheal aspiration
Esophagus	Reduced motility and pressure, dilation, dysphagia frequent
Stomach	Dilation, delayed emptying with food retention
Small bowel	Usually normal
Colon	Megacolon, fecal impaction, symptoms similar to irritable bowel syndrome; rarely volvulus
Anal sphincter	Myotonia demonstrable

children (11). Conduction defects are seen on electrocardiography (ECG) in many affected adults, even in the absence of cardiac symptoms; varying degrees of heart block are the most common finding. More detailed studies with the His bundle ECG have confirmed these abnormalities (12) and suggested that widespread degeneration of the conducting tissue occurs when the myocardium as

a whole is relatively normal. Thus, all patients should receive regular ECG monitoring annually, supplemented when needed by 24-h monitoring and more detailed studies. It should also be noted that intra-Hisian conduction delay might be present in the absence of ECG abnormalities. Unfortunately, the role of electrophysiological testing in patients with normal ECG has not been established (13); however, in patients with symptoms such as syncope or with a family history of sudden death, or both, electrophysiological testing is strongly advised (14). The magnetic resonance imaging analysis of cardiac morphological and functional abnormalities may become useful for determining the necessity of electrophysiological studies (15). Insertion of a pacemaker should be seriously considered in patients with significant conduction problems (12,16). Drugs such as quinine, which may depress conduction, should be avoided. Although the prevalence of congestive heart failure is low among patients with DM1, tissue Doppler echocardiographic studies showed that up to 29% of asymptomatic patients have left ventricular systolic dysfunction (17,18). Bouts of various arrhythmias may occur, notably atrial flutter/fibrillation and ventricular tachyarrhythmias. These arrhythmias appear to be attributable to cardiomyopathy rather than abnormal autonomic regulation of the heart (19). Although the incidence of ventricular tachyarrhythmias may not be sufficiently high to justify implantable defibrillator therapy routinely when permanent pacing is indicated (13), defibrillator implantation has been proven to be life saving in some cases (20). The importance of sudden death in DM1 has recently been highlighted by Groh et al. (21), who found that patients with a severe abnormality on their ECG (rhythm other than sinus, PR interval of 240 ms or more, QRS duration of 120 ms or more, or second- or third-degree atrioventricular block) were at risk of sudden death.

In most cases, neither smooth nor cardiac muscle is significantly affected without some degree of skeletal muscle involvement; thus, these systems are not helpful as predictive tests or in genetic counseling, and they should not be used as such now that accurate mutational testing is possible. Although occasional patients have presented with smooth or cardiac muscle problems, they usually prove to have definite myotonia and weakness as well, even though the patient may not have complained of this.

Respiratory problems in DM1 are partly attributable to aspiration and to diaphragmatic involvement but may also reflect a central abnormality. Alveolar hypoventilation is well documented (22) and is frequently associated with hypersomnia. Use of domiciliary-assisted ventilation in patients with DM1 has been shown to be associated with prolonged survival and a sustained improvement in arterial blood gas tensions (23). Postanesthetic respiratory depression is a serious hazard; consequently, great care should be taken if anesthesia is required, even in young and mildly affected patients (24).

In spite of our awareness of the early mortality of DM1, with an average age of death at 53 and over 70% of patients dying from cardiorespiratory complications (25), there appears to be little impact on improving these devastating figures and a controlled clinical trial of cardiorespiratory intervention is sorely needed.

**130.2.1.4 Ocular Abnormalities.** Although cataracts have been well recognized as a complication of DM1, involvement of the eye is more extensive than cataract alone (Table 130-7).

Lens opacities are rarely seen in young children, but this problem steadily increases with age, whereas clinically evident cataract is present by middle age in most patients (Figure 130-3). Lens opacities have a characteristic refractile, multicolored appearance when viewed with the slit lamp or “Christmas Tree” cataracts, although more mature cataracts may be difficult to distinguish from other types. Opacities are characteristically subcapsular rather than nuclear. No other myotonic disorder or primary muscle disease shows lens opacities of this type, with the exception of DM2; however, multicolored opacities can also occur in healthy individuals from the general population without the DM1 mutation (26). Although slit lamp examination for lens opacities is an important aid in the differentiation of atypical cases, it should not be used in presymptomatic detection. Retinal abnormalities are less well recognized and may be macular or peripheral. Electroretinography is a sensitive method of detecting changes, particularly when cataract obscures an ophthalmoscopic view. The retinopathy occurs independent of therapy with quinine or other drugs. The other ocular abnormalities are of less significance clinically, apart from ptosis, which is one of the most sensitive signs of the disorder in asymptomatic relatives or in old photographs. Clinically significant myotonia of the eyelids and ocular muscles is less common than in myotonia congenita. External ocular muscle weakness can also be seen.

**130.2.1.5 Brain Abnormalities.** Central nervous system (CNS) involvement is one of the most important and least well understood abnormalities in DM1. Since the earliest studies of DM1, abnormalities in the brain have been recognized, particularly when onset occurs early in life. Although major cognitive changes are unusual in adults, frontal executive dysfunctions including apathy, reduced initiative, stubbornness, and avoidant personality trait often render DM1 patients socially disadvantaged (27,28). Excessive daytime sleepiness is a frequent complaint of patients with DM1, and the condition cannot be fully attributable to central and obstructive sleep apnea, which are also common in DM1. Hypersomnolence in DM1 resembles narcolepsy by accompanying short sleep latency, the presence of sleep-onset rapid eye movement periods, and a dysfunction of the hypothalamic hypocretin system (29). Focal atrophy with progressive white matter lesions can be found on imaging studies in adults (30). Neurofibrillary tangles containing tau protein are increased in

**TABLE 130-7 Ocular Abnormalities in Myotonic Dystrophies**

number, and inclusion bodies have been noted in the brainstem (31,32). Abnormalities in auditory and other evoked potential studies (33), and in central oculomotor control further suggest widespread CNS dysfunctions (34). There has been recent increased interest in the CNS involvement in DM1. Weber et al. performed neuropsychological tests, structural cerebral MRI and 18F-deoxy-glucose PET (FDG-PET) in 20 DM1 and nine DM2 patients and matched healthy controls (35). DM1 and DM2 patients typically showed pronounced impairment of nonverbal episodic memory and a reduction of the global gray matter especially in the frontal and parietal lobes. A reduction in bilateral hippocampal volume was correlated specifically to both a clinical score and episodic memory deficits. White matter lesions were found in over 50% of patients, and were correlated to psychomotor speed. FDG-PET revealed a frontotemporal hypometabolism, independent of the decrease in cortical gray matter. All abnormalities were similar in both DM1 and DM2 patient groups but were more pronounced for DM1. This study confirmed that cognitive deficits tend to be more severe in DM1

than DM2 that decreases in cerebral gray matter may be independent of metabolism and that some of the characteristic cognitive changes are linked to specific structural changes. A comprehensive neuropsychological study and personality assessment, using the Millon Clinical Multiaxial Inventory (MCMI)-II on 121 patients with DM1 and 54 control patients, found that cognitive impairment particularly affected frontoparietal regions in DM1 and this deficit was correlated with CTG expansion in leucocytes (36). A further study investigated 50 DM1 and 14 DM2 patients and performed MRI to assess white matter lesions, neuropsychological profiling and SPECT analysis (37). The authors described a temporo-insular diffuse lesional pattern on MRI, which was specific for DM1. They also confirmed more severe cognitive involvement in DM1 than DM2. In conclusion, these studies confirm that there is significant cognitive involvement, especially in DM1, although a characteristic structural and neuropsychological profile has not been fully characterized.

**130.2.1.6 Endocrine Abnormalities.** Widespread endocrine disturbance exists in DM1 (Table 130-8 (3)), but the most significant abnormality observed clinically is testicular atrophy, which consists of a primary tubular degeneration with fibrosis and hyalinization and relative hypertrophy of Leydig cells. In spite of reduced spermatogenesis, patients may be fertile, even in the presence of clinical testicular atrophy. Male infertility is still a frequent occurrence. Elevation of blood follicle-stimulating hormone (FSH) is the main biochemical feature, with a lesser degree of luteinizing hormone (LH) elevation, whereas testosterone levels are commonly normal, in keeping with the conservation of Leydig cells and the normal secondary sex characteristics.

No directly comparable gonadal problem exists in women, but there is a high incidence of reproductive loss (one-third of all pregnancies in studies undertaken by Harper). Whereas losses late in pregnancy are probably

related to the congenital form of the disease (see later), the early pregnancy loss is more likely to reflect an endocrine disturbance, or possibly uterine smooth muscle involvement. This latter factor again becomes important in causing delayed and incoordinated labor.

Diabetes mellitus is a well-recognized problem, but clinical diabetes occurred only in 6% of the Harper's series (38). In contrast, biochemical studies have shown that abnormalities of insulin metabolism are almost universal. The main feature is insulin resistance, now recognized as resulting from reduced insulin receptor (39). Insulin resistance in DM1 is accompanied by abnormal levels of cytokines, such as leptin, tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), tumor necrosis factor II (TNFII) receptor, and testosterone, and by altered glucagon-like peptide-1 and adrenocorticotrophic hormone /cortisol responses (40,41). Additionally, insulin secretory dysfunctions may have a significant role (42).

Several other clinical features may reflect endocrine abnormalities, notably early balding, which is frequent in men, and the skeletal changes, which include cranial hyperostosis, enlargement of air sinuses, and frequently, a small pituitary fossa. Adrenocorticoid and mineralocorticoid metabolism are also impaired in DM1 (43,44).

**130.2.1.7 Congenital and Childhood-Onset Myotonic Dystrophy Type 1.** It is important to recognize that DM1 may also occur in neonates and young children, and that these forms, in particular congenital DM1, show marked clinical differences from the more classical 'adult' form (Table 130-9). Furthermore, unlike most genetic disorders, in which severe and mild forms run separately in families, the congenital and adult forms of DM1 are usually seen together, typically with the mother, who is often mildly affected, as the transmitting parent. An explanation for this phenomenon has come from our better understanding of the molecular

**TABLE 130-8 Endocrine Abnormalities in Myotonic Dystrophies**

Organ	DM1	DM2
Testis	Testicular atrophy (60–80% clinically); degeneration of tubular cells; hyperplasia of Leydig cells; serum testosterone slightly reduced	Testicular dysfunction (~65%) with low or low-normal testosterone levels, and oligospermia (59)
Ovary	No consistent evidence of abnormality; high fetal loss	Increased pregnancy loss reported (60)
Pituitary	Increased FSH levels; slightly increased LH levels; increased LHRH response Hyperresponsiveness to exogenous growth hormone <sup>a</sup>	Increased serum FSH
Pancreas	Increased insulin resistance Clinical diabetes <sup>a</sup>	Manifest diabetes (~25%; (59)) with insulin resistance
Thyroid	No evidence of abnormality; but myotonia sometimes found in hypothyroidism	Reported but probably coincidental
Adrenal; parathyroid	No consistent abnormality found

<sup>a</sup>Rare or inconsistent abnormalities.

genetics of DM1 and is discussed in more detail later in the chapter.

Clinical features of congenital DM1 have been extensively reviewed in Harper's book (3). The hallmarks of the congenital form are generalized hypotonia and facial diplegia. Other features include jaw weakness with respiratory and feeding difficulty in neonates, and intellectual disability is common in those who survive the neonatal period. Talipes and arthrogryposis are frequent, and a variety of other features suggesting intrauterine onset of muscle dysfunction occur, such as hydramnios, diaphragmatic hypoplasia and thin ribs, as well as poor fetal movements. Many affected infants die soon after birth from respiratory problems and many neonates are not diagnosed rapidly during early life.

Infants and young children with the congenital form of DM1 do not show clinically evident myotonia, although some myotonic potentials are usually visible electromyographically. A young child with myotonia is much more likely to have one of the non-dystrophic myotonic disorders than DM1. The differential diagnosis of congenital DM1 includes other causes of infantile hypotonia, such as congenital myopathies, spinal muscular atrophies, Pompe's disease, and various CNS disorders, including cerebral palsy. The X-linked neonatal myotubular myopathy is particularly likely to be confused, although there are clear differences in muscle histology and molecular diagnosis is differentiating (see Chapter 127).

The facial diplegia and characteristic "tented mouth" should permit instant suspicion of congenital DM1 in many cases (Figure 130-4) and becomes even more characteristic as the child grows older (Figure 130-5). Some patients may have few neonatal symptoms but may present in later childhood with mental retardation or speech problems. By the second decade of life, myotonia is usually clinically apparent and the progressive "adult" features begin to appear. Many affected children appear to improve markedly during their first decade. In the original study by Harper (45), only two patients with congenital DM1 had died after the neonatal period and no survivor had failed to walk, although at least two-thirds were

significantly cognitively impaired. Brain MRI of congenital DM1 patients typically shows ventriculomegaly and moderate/severe hyperintensity of the posterior white matter at all ages. The duration of assisted ventilation during the neonatal period is a significant prognostic factor for subsequent morbidity and developmental delay (46).

The combination of a relatively good prognosis for life with a poor prognosis for mental function requires careful consideration both when genetic counseling is given to affected women and when resuscitative measures are being attempted in a newly diagnosed congenital case. The long-term outlook for patients with congenital DM1 is poor for living an independent life and employment. Physical deterioration and complications may accelerate mortality in those older than 30 years.

The childhood onset DM1 is in many ways intermediate between the congenital and adult-onset types (47). Cognitive and behavioral problems are prominent in this

**FIGURE 130-4** Congenital myotonic dystrophy. Patient with his mildly affected mother. Note facial diplegia with "tented mouth."

group, most notably with attention deficit hyperactive disorder and anxiety disorder (48), but the early perinatal problems are absent.

### 130.2.2 Clinical Manifestations of Myotonic Dystrophy Type 2/Proximal Myotonic Myopathy

Centers specializing in unusual myotonic disorders, notably, those of Ricker et al. in Germany (49) and Thornton et al. in the United States (50), were able to separate a group of patients with a DM1-like disorder, which does not show the CTG expansion. This disorder was named proximal myotonic myopathy (PROMM) initially because of conspicuous weakness and atrophy of proximal muscles (49). It soon became clear that the condition occurred in most Indo-European populations, although it seems to remain especially prominent in Germany (51).

There have also been reports of DM1-like families with no CTG repeat expansion, in which the distribution of muscle weakness and atrophy differed from PROMM. Families with one of these myotonic dystrophy-like diseases, designated myotonic dystrophy type 2 (DM2), were identified in Minnesota, and the DM2 locus was mapped to chromosome 3q (52). Subsequently, this locus was confirmed to be also the locus of PROMM in German families (53). Cross-examination of these families by German and American investigators led to the conclusion that DM2 is the same disease as PROMM. The genetic mutation of DM2/PROMM was found to be an expansion of CCTG repeats in intron 1 of the *ZNF9* gene (54), which accounts for the mutation in most PROMM and other atypical myotonic dystrophy-like families.

An autosomal dominant family with multisystemic myotonic myopathy with frontotemporal dementia was described with a new disease locus, proposed to be called “DM3”, and mapped to 15q21–q24 (55). These and other similar patients were subsequently found to be due to a mutation in the gene valosin-containing peptide (VCP) and mutations in VCP have been found to cause several myopathy phenotypes associated with a vacuolar myopathy and not myotonic discharges (56). There are also a handful of other families with multisystemic myotonic myopathies without DM1 or DM2 mutations and therefore “DM3” may still be described (2).

The main clinical features of DM2 are compared with DM1 in Table 130-3. In general, the disorder is relatively mild and slowly progressive, with proximal weakness and wasting predominant but not exclusive. There can be coexistent weakness in deep finger flexor muscles, mild facial involvement, and preservation of bulbar function and manual skills, and mild or clinically absent myotonia. Cardiac involvement is milder than in DM1, but arrhythmias are frequently detected. The atrioventricular block is infrequently found, but sudden cardiac deaths with histological cardiac abnormalities have been reported

(see Table 130-6) (2,57). Cataracts are present as with DM1 (see Table 130-7). In DM2, some endocrine abnormalities, such as testicular dysfunctions and insulin resistance, are as common as, but milder than, those found in DM1 (see Table 130-8). Frontal executive dysfunction (28) is reported, but the social and cognitive abilities are typically mild, and hypersomnolence and mental retardation are not prominent findings in DM2 (2). Severe muscle and joint pain, and calf muscle hypertrophy, may further differentiate DM2 from DM1. Gastrointestinal involvement has not been systematically studied, but DM2 patients often have similar but milder symptoms than in DM1. Muscle pathology is also comparable in some cases, although type 2 fiber atrophy, “denervation-like” changes, and the absence of sarcoplasmic masses are characteristic of DM2 (Table 130-10) (2,58). Serum creatine kinase and gamma glutamate transferase levels frequently show a mild increase (2,59). Wider features such as deafness and hyperhydrosis may occur (51,60), whereas some patients with the DM2 mutation show only subtle and nonspecific clinical signs.

Inheritance of DM2 is autosomal dominant, but anticipation may not occur and age of onset may not be related to the size of the quadruplet repeat expansion. No congenital or severe childhood cases have been recorded in families to date. It is noteworthy that even rare patients with homozygous CCTG repeat expansions show no congenital phenotype (61). There are no clear effects of the gender of the transmitting parent on the offspring’s phenotype (2,60).

### 130.3 DIAGNOSTIC INVESTIGATIONS OF MYOTONIC DYSTROPHY TYPES 1 AND 2

Molecular genetic analysis (see full description later) is now the most significant test in relation to both diagnosis and prediction, because it can be conveniently undertaken on a blood sample. Polymerase chain reaction (PCR) and Southern blot analyses are primarily

**TABLE 130-10 Muscle Histology in Myotonic Dystrophies**

Characteristic Features	DM1	DM2

used to detect *DM1* and *DM2* mutations. Repeat-primed PCR allows for quick detection of expansion mutations, although it does not determine the expansion size (62). In *DM2*, conventional PCR/Southern-blot protocols detect the *DM2* mutation in only 80% of subjects with known expansions. Thus, an additional *DM2* repeat assay (RA) that consists of amplifying the CCTG repeat by PCR and probing the resultant product with an internal probe is recommended to ensure greater than 99% specificity and sensitivity for known expansion (2,59). The diagnostic values of in situ hybridization-based analyses for the *DM2* mutations have also been investigated (63).

A clinical diagnosis should also be made in symptomatic patients, as some patients now achieve a genetic diagnosis before developing clinical symptoms. Muscle biopsy is no longer a primary means to diagnose *DM1*, although it provides valuable samples for research and may still have been performed by clinicians who suspected a myopathy but not *DM1/2*. A striking muscle immaturity seen in congenital *DM1*, with centrally placed nuclei and abundant satellite cells, provides a valuable distinction from other congenital neuromuscular disorders, especially X-linked myotubular myopathy, in which satellite cells are markedly reduced.

Stored frozen muscle samples should also be remembered as a useful source for DNA analysis in deceased patients when relatives are requesting prediction. Muscle is of special importance in allowing confirmation or exclusion of the congenital form in material from patients who have died.

## 130.4 GENETICS

### 130.4.1 Genetic Aspects of Myotonic Dystrophy Type 1

Early studies established an autosomal dominant inheritance pattern in *DM1* but highlighted the remarkable variability in phenotype and age at onset. Although our understanding of the genetics of anticipation and congenital *DM1* has remarkably increased, there are still unsolved questions with these phenomena. Furthermore, the genetics of *DM2* is distinct in many aspects from *DM1* in spite of the fact that both diseases are caused by repeat expansion mutations. Several detailed reviews are available (64,65).

**130.4.1.1 Gene Mapping of Myotonic Dystrophy Type 1.** The identification of the *DM1* gene was the result of pure gene mapping and positional cloning research, carried out over a period of almost a decade. After genetic linkage to the secretor and Lutheran blood group in 1971 and assignment to chromosome 19 in 1982, the gene locus had been narrowed down to a restricted region of 19q, which underwent progressive physical mapping and cloning (reviewed in reference (3)).

**130.4.1.2 Unstable DNA Sequence in Myotonic Dystrophy Type 1.** The specific change, a DNA expansion mutation, was recognized at the end of 1991 (66,67),

and was rapidly confirmed (68). After the discovery of the CAG expansion in Kennedy's disease and the CGG repeat in fragile X syndrome, the CTG repeat expansion in the 3'UTR of the *DMPK* gene was identified as the myotonic dystrophy mutation (69–71), which is now known as the *DM1* mutation.

#### 130.4.1.3 Anticipation and Myotonic Dystrophy

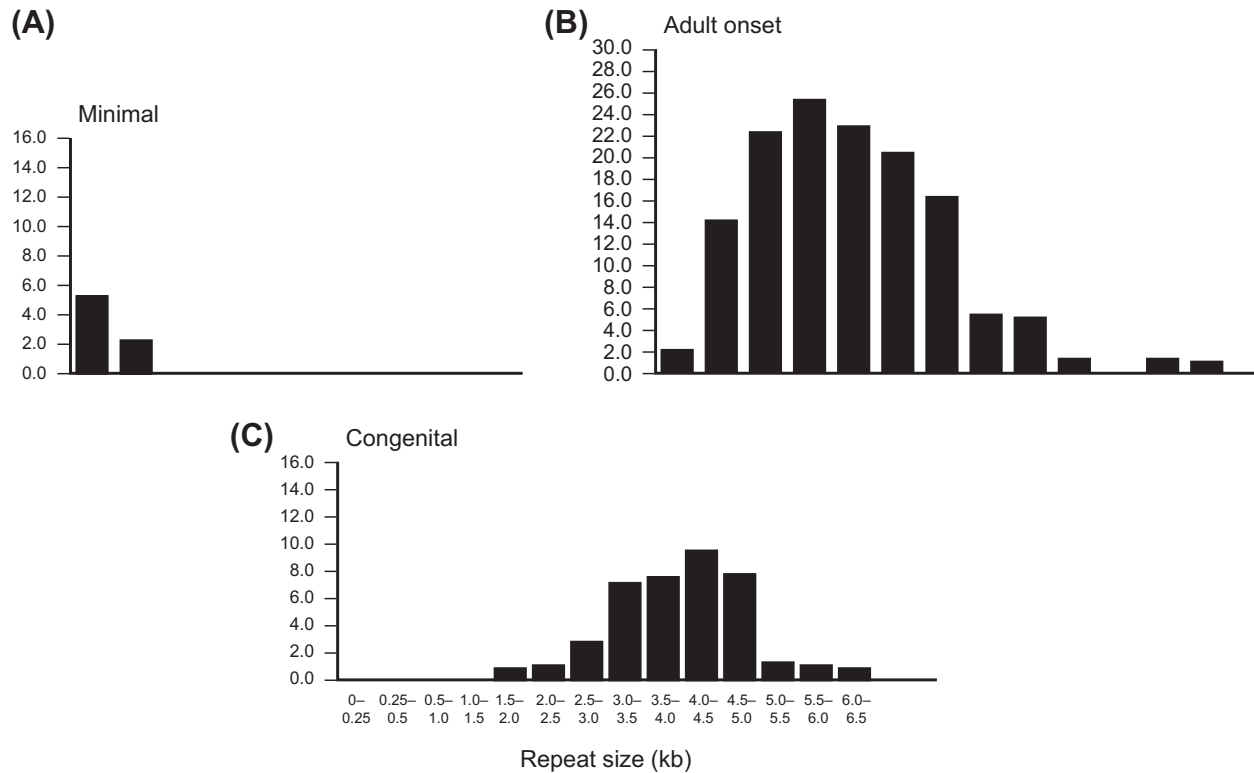

**Type 1.** The suggestion that *DM1* might occur with earlier onset and progressively more severe course in successive generations was proposed as long ago as 1918 by Fleischer, who found that patients with muscle disease could frequently be linked with past generations through individuals showing cataract as the only clinical manifestation. Although other clinical and family studies of myotonic dystrophy supported this, the analysis presented by Penrose (72) disputed anticipation as a result of the inherent ascertainment biases, together with the extreme intergenerational variability of myotonic dystrophy, which he suggested might result from effects of the opposite allele.

The fascinating story of how anticipation was recognized, forgotten, and then rediscovered was described by Harper et al. (73). By 1989, it had become clear from the work of Howeler that the biases postulated by Penrose were inadequate to explain anticipation (74), whereas the similarity with fragile X mental retardation had also been recognized. Anticipation is now recognized as a major criterion for any disorder attributed to an expanded trinucleotide repeat and has been validated in several independent analyses of *DM1*. Most of the apparent anticipation susceptibility reported in a wide range of other disorders may still reflect the biases documented by Penrose many years ago (75).

#### 130.4.1.4 The *DM1* Mutation: Clinical–Molecular

**Correlations.** Once the expanded CTG repeat sequence had been identified as specific for *DM1*, the question immediately arose as to what extent its variability could be correlated with severity and clinical phenotype. Correlations have been confirmed in numerous independent series (reviewed in references (3,65,76)). Figure 130-6 shows the relationship of severity and molecular defect when patients are classified into the three broad groups: severe childhood disease, classic adult-onset *DM1*, and minimal disease of later life. The overall difference between the groups is clear, but there is considerable overlap between the categories and the range of expansion for each group, making considerable caution necessary in using this information for prognosis in an individual case. Gennarelli et al. (77) have found that repeats of less than 100 were rarely associated with significant neuromuscular disease. When age at onset is used as the criterion instead of repeat size (Figure 130-7), a comparable correlation is seen. This finding would be expected in view of the close relationship between age at onset and severity of clinical disease.

The extremes of the distribution for age and severity are of particular interest, as among the most severe cases of congenital onset, expansions of a remarkable degree

**FIGURE 130-6** Correlation of phenotype and genotype in myotonic dystrophy. The three main clinical groupings in myotonic dystrophy are shown, together with the range of expansion in the CTG repeat. (A) Minimally affected individuals; (B) Classic phenotype with adult-onset; (C) Severe congenitally affected patients. Note the overlap between groups, even though the mean values are clearly distinct. (*Cardiff series; Data from Harley, H. G.; Brook, J. D.; Rundle, S. A., et al. Expansion of an Unstable DNA Region and Phenotypic Variation in Myotonic Dystrophy. Nature 1992, 355, 545–546 (67).*)

may occur, sometimes exceeding 2000 repeats (78). Among the minimally affected cases, particularly when these are restricted to those older individuals with cataracts alone, there is a consistently small expansion. The smallest expansions of all are seen in those parents in the older generation who are entirely normal clinically, but in whom one member of a couple consistently showed an expansion of 38–49 copies, compared with the normal range of 5–37 copies. Such individuals can be considered premutations, comparable to the normal male gene transmitters seen in fragile X syndrome. These cases are of particular significance in relation to the origins and persistence of the disease, as will be considered later. An extensive study of premutations from Spain has shown that no individual with less than 55 repeats showed any clinical abnormality, but that there was significant meiotic instability in the range of 30–55 repeats, especially when transmitted by men (79).

**130.4.1.4.1 Intergenerational Changes.** As already noted, major anticipation had long been recognized in DM1. The relationship between age at onset in parent and in offspring of DM1 families, noted by many previous studies extending back as far as that of Julia Bell in 1947, shows a corresponding relationship for the molecular defect (reviewed in References (3,65,76)). It is clear from these and similar data presented by others that the genetic instability of the DM1 mutation is likely to be the major factor underlying the observed anticipation.

For both the age at onset data and the molecular expansion, a small proportion of the parent–child pairs not only do not show anticipation but show later onset and smaller repeat sequence in offspring than in the parent. Pooled data from a number of centers have allowed this observation to be confirmed and extended (80), and it seems that about 6% of transmissions show a decrease in size of the repeat sequence, although the likely selection biases involved in the study of two-generation families make it difficult to attain precision. It is also of interest that in some of the cases in which the sequence decreased in size, anticipation was still observed in terms of earlier age at onset, although again this observation could be biased. A final point of relevance regarding those transmissions showing a decrease of repeat size is that they occur primarily during male meioses, an observation that leads to discussion of the important sex-related differences in transmission of the DM1 mutation.

**130.4.1.4.2 Parental Origin Effects.** Although DM1 behaves as a classic autosomal dominant trait in respect of equal incidence in, and transmission by, each sex, it has long been noted that this basic equality masks important sex differences in terms of transmission of the disorder. The most striking feature, mentioned earlier and discussed more fully later, is the observation that almost all congenital cases originate from an affected mother. Less obvious but of equal importance is the preponderance of men in the grandparental generation of

such congenital cases and in the earliest affected ancestors, usually showing only minimal disease (81,82).

These observations have now been confirmed and extended at the molecular level (reviewed by Harper (3)), although a number of aspects remain to be resolved. First, as already mentioned, it is the severe congenital cases that show the largest repeat sequences, some of which may be extreme. Paternal inheritance of congenital DM1 has been described but is very rare (83,84). Most cases in which the sequence has reduced in size are paternal in origin and putting these two observations together suggests an upper limit to expansion during male meiosis that is not present during female meiosis. This may be an important factor in explaining the maternal transmission of the congenital form. The study of those patients with minimal disease has confirmed its predominantly male origin in the earliest available ancestors (81,82). Most of the minimally affected progenitors have cataracts and are men. In those cases in which both parents are entirely normal, it has been the male parent in most instances (around 70%) who has shown the presence of a “pre-mutational” expansion. These data suggest a paradox at first sight such that there appears to be predominant male transmitted expansion and anticipation at the minimal end of the severity range, as compared with predominant female-transmitted expansion at the severe end (see Reference (65)).

The considerable degree of infertility and oligospermia found in many men with DM1 is a complicating factor, but it is clear that the degree of repeat sequence expansion seen in sperm differ considerably from that found in blood (85,86). Small pool PCR-based analysis of sperm from men with DM1 showed high levels of repeat-length variation. The length variation was heavily biased toward further expansion, with the largest length changes observed for premutation and protomutation alleles and the highest frequency of contractions was found in full mutation alleles (85). Embryos and gametes obtained during preimplantation genetic diagnosis have shown that there were significant increases in the number of repeats in embryos from female patients with DM1 and in their immature and mature oocytes, whereas, in spermatozoa and embryos from male patients, smaller increases were detected (87). These data are consistent with the parental origin effect observed in the intergenerational changes of the repeat size. Interestingly, the size of expanded allele in sperm in two male patients with DM1 did not change in 4 years. A study of siblings with DM1 showed that birth order, intergenetic interval, oldest sibling’s CTG repeat, parental age or parental CTG repeat size did not exert any significant influence on siblings’ genotype or phenotype (88). In oocytes, the enlargement of the repeat had occurred at the germinal vesicle stage, that is, either during premeiotic proliferation of oogonia or during prophase I of meiosis I (87). This implies DNA repair-based expansion of the repeat in these cells that have undergone a long period of quiescence, as proposed by Pearson (89).

**130.4.1.4.3 Molecular Basis of Congenital Myotonic Dystrophy Type 1.** The parent-of-origin effects described earlier go some way to explaining the severity and maternal transmission of the congenital form of DM1. On average, these cases show the largest expansions in the gene, whereas a combination of diminished male fertility and possible selection against sperm carrying very large expansions could explain the maternal transmission. A further aspect that has been clarified is why congenital cases almost always arise from mothers who either have, or will later develop, classical adult DM1, and only very rarely from those with mild late-onset disease such as cataracts alone (90). This can now be explained by the limitation of intergenerational change in the expanded sequence, so that it is unusual for a change sufficient to produce the congenital form to occur without an intervening generation. Congenital cases can be separated more clearly from others if the size of the parental repeat is taken into consideration, as well as that of the patient alone (reviewed by Harper (3)).

Despite these advances, a number of aspects of congenital DM1 remain without satisfactory explanation. The range of repeat size in this group shows extensive overlap with those showing no congenital or even childhood onset. The size of parental expansion may explain the origin but not the congenital onset itself, unless there is some more direct effect of parental phenotype on the disease in the offspring. The suggestion of an intrauterine maternal effect, proposed many years ago but never validated is still not entirely obsolete in this respect.

DNA from congenital DM1 patients showed complete methylation of restriction sites surrounding the CTG repeat (91), and methylation prevented binding of the zinc-finger protein CTCF to two sites on the DNA flanking the CTG repeat (92). These two sites formed insulators, and CTCF binding to these sites prevented promoter–enhancer interactions. Therefore, the DM1 locus methylation in congenital DM1 would disrupt insulator function. The effects of other loci interacting with the DM1 gene could also be relevant. Mitochondrial dysfunction has been suggested, but no molecular mitochondrial defect has been shown (93).

Defective muscle differentiation during the development has been well documented in studies of the skeletal muscle and myoblasts from subjects with congenital DM1 (92,94). However, the molecular mechanism through which the very large CTG repeat causes this muscle immaturity remains unknown (discussed later). In recent studies, cell-culture and transgenic mouse models overexpressing the 3'UTR of the *DMPK* gene showed defective muscle differentiation (95,96). Furthermore, this transgenic mouse model developed muscle atrophy and, later in life, hypertrophic cardiomyopathy, myotonic myopathy and hypotension traits (97). The overexpression of the *DMPK* 3'UTR may therefore cause features that resemble congenital DM1.

Further studies in muscle and other tissues will be needed to elucidate the molecular mechanisms leading to the congenital DM1 phenotype.

**130.4.1.4.4 Homozygosity for the DM1 Gene.** Molecular analysis has shown at least seven homozygotes for the minimal expansion mutation (98) that appear to be healthy. In contrast, two siblings carrying 43/180 and 43/500 CTGs showed an adult-onset phenotype (99). Neither of these cases had two fully expanded alleles, so it is not yet clear whether homozygotes generally will differ from heterozygotes, as has now been shown for Huntington's disease (100).

**130.4.1.4.5 Reversal of the Myotonic Dystrophy Type 1 Mutation.** Reduction of the DM1 mutation to the normal range has been observed in several individuals (81,82,101) who were detected as a result of discrepancy between a haplotype analysis suggesting transmission of the DM1 gene and a normal mutation analysis result. All cases so far have been of paternal origin, and it is not clear whether the process reflects a selection of sperm in the parent or some more direct molecular change in the early embryo. These cases are of practical importance in risk prediction for such individuals and their families, although it must be stressed that true non-penetrance of the gene in the offspring of an established case is exceptionally rare.

**130.4.1.4.6 Somatic Instability and Mosaicism.** From the earliest observations, it was clear that somatic instability was also a feature of the DM1 mutation, with analysis of blood leukocytes showing the expanded sequence as a “smear” or diffuse band (67). This suggests a range of fragment sizes, rather than the usual sharply defined band. This phenomenon has now been explored in greater detail (80,86,102) and occurs generally in trinucleotide repeat disorders, in particular those characterized by extreme expansions.

All the initial molecular studies relied on blood samples, and therefore the important question arose as to what extent tissue variation in the repeat sequence occurred. Autopsy studies have shown significant variation, whereas analysis of muscle biopsy samples has suggested that greater expansion of the repeat is generally seen in muscle than in blood (65); however, there is also greater variability. The repeat size in blood shows a closer correlation with clinical severity than that in muscle. This may reflect the inevitably localized origin of a muscle sample compared with a constantly circulating blood sample. It has the practical implication that blood probably remains the most secure guide to prognosis, insofar as it is wise to attempt this at all. In terms of prognosis, for the next generation, it may well be that sperm analysis will prove of practical relevance when methods of single sperm analysis become more generally available, given the differences between somatic tissues and germline.

A second field of relevance in relation to somatic instability is the question of change over time.

Those who show most spread in expansion are generally older and are relatively severe cases. It was noted early on that this was neither shown by older minimal cases, nor by chorion villus prenatal samples showing very large expansions (103). Analysis of blood samples taken at intervals of several years (104) has confirmed increased spread of repeat size in later samples, although no overall size increase was seen in muscle biopsy samples taken at intervals. These studies also illustrate a third relevant factor, that somatic variability is related to the initial size of the expansion, being greater for large expansions than for small expansions over a prolonged time period. What relationship such somatic change will have to the pathogenesis of the disease in different tissues and in different types of the disease is a point of considerable interest which future work should clarify.

True mosaicism usually implies the existence of clearly separate genetic cell lines in a single individual, as seen in cytogenetic disorders and in an increasing number of genetic conditions in which it is of germline origin, with a mixture of normal and abnormal tissue. Although individuals with fragile X syndrome showing clearly separate lines have been identified, this is not the main feature of trinucleotide repeat disorders, in which somatic instability is usually reflected in a more general spread of variation and in tissue heterogeneity. Any true mosaicism would be expected to result from early embryonic rather than germline variation. Monozygotic twins give some indication of the likely extent and role of such development differences and affected twin pairs generally show close similarity of both clinical features and repeat size.

**130.4.1.4.7 Mechanism of Instability of the CTG Repeat in Myotonic Dystrophy Type 1.** The molecular mechanism of changes in the CTG repeat length has been investigated by in vitro and in vivo models. Mouse models expressing a transgene containing expanded CTG repeats have proved to be particularly effective because they could replicate both germline and somatic instability with a strong bias toward expansions and the sex- and size-dependent characteristics (105–108). The size of expanded CTG repeats also showed age-dependent increases in somatic tissues of these animals as shown in humans (108), but there have been no mouse models exhibiting a “big jump” of the CTG repeat toward further expansion into the congenital DM1 range. Nevertheless, these mouse models provided data that cannot be easily obtained in human samples regarding the instability of the CTG repeat. Examinations of germline tissues in these animals showed that strong mosaicisms toward expansions were already observed in spermatogonia before meiosis, and no significant difference in mosaicism was detected between spermatogonia and spermatozoa, arguing against continued expansions during postmeiotic stages (109). These observations are in agreement with the human data suggesting that germinal expansions are produced at the beginning of spermatogenesis by a meiosis-independent mechanism. Another important finding

derived from these mouse models is that the repeat-length mutations appear to occur independently of DNA replication. There is no correlation with the levels of somatic mosaicism observed and cell turnover rates between tissues, and the brains of adult mice increase the degree of mosaicism in spite the post-mitotic state of neurons by four months of age (105). More recent studies using transgenic models have suggested that genes controlling DNA mismatch repair (such as Msh2, Msh3, and Msh6) play a critical role in the mutation process (110). Crossing mice transgenic for expanded CTG repeats with Msh2-deficient mice suggested that the absence of Msh2 shifts the instability toward contractions, both in tissues and through generations (111). Although Msh3 deficiency completely blocked the somatic instability, a lack of Msh6 resulted in a significant increase in the frequency of somatic expansions. Competition of Msh3 and Msh6 for binding to Msh2 in functional complexes with different DNA mismatch-recognition specificity may explain these data (110). CTG repeats are known to be able to adopt unusual secondary structures, such as “hairpins,” that differ from the usual double helical (B-DNA) structure (89). These unusual structures may be targets of mismatch repair.

**130.4.1.4.8 Origins of the Myotonic Dystrophy Type 1 Mutation.** Numerous family and population studies of DM1 were carried out before identification of the gene and mutation, which attempted to analyze mutation rate and related aspects such as genetic fitness, prevalence, and geographic variation. All were fraught with difficulty because of the extreme clinical variability of the disorder (38). Now that the unusual mutational mechanism underlying DM1 is understood, we can see why these early studies encountered such problems and can also begin to explain some of the apparent anomalies. The discussion here focuses on two separate but related questions: the origins of clinically identifiable cases of the disorder, and the ultimate origin of the initial expansion in the DM1 repeat sequence.

Regarding the origins of the clinical disorder, the validation of anticipation as a biological process has already been discussed. Clinically significant cases of DM1 do not arise de novo, but from a parent who has an expanded repeat sequence; usually, but not always, showing some minimal clinical features such as relatively early onset cataracts in comparison to senile cataracts. When the parents of patients with mild phenotypes are assessed and are found to be normal, one (usually the father) has always shown to have an expansion. It is these clinically normal individuals, usually with 38–49 repeats, who provide the link between different DM1 families so frequently shown by genealogical studies (81,82). The demonstration that unselected patients with cataracts do not show a markedly increased frequency of small expansions in the DM1 gene (112,113) makes it unlikely that those ancestors carrying small “premutation” expansions are or were clinically abnormal, which is a point

of considerable significance in relation to possible prevention in a population. The extent to which minimally affected individuals and normal premutation carriers are included in any study of genetic fitness and fertility will obviously have a profound influence on the results. It is also highly relevant to the question of why the disorder does not die out, as discussed later. How far back the instability of the expanded DM1 repeat extends, and to what degree, is an important question that remains largely unanswered.

Detailed analysis of a very large Dutch kindred studied over many years has shown that increased repeat size, clinical anticipation, and eventual elimination of the gene occurred in all branches within five generations (114). Premutation alleles identified both in distant relatives of probands and, more rarely, in unaffected spouses were found to be highly unstable and liable to expand in succeeding generations, particularly when transmitted by a man (79). These data suggest that premutation carriers are at high risk of having affected offspring within a limited number of generations, leading to elimination of the mutation by anticipation. Although there has been a report of a DM1 family in which the number of CTG repeats remained in the minimally expanded range through at least three, and possibly four, generations (115), premutation alleles within most DM1 families may not be the long-term source of new DM1 families. Interestingly, alleles within the high end of the normal size range have shown occasional expansion-biased instability during paternal transmissions (79). When they are put together, these data support the theory that the prevalence of DM1 is maintained by expansion of the high end of normal-size alleles. There is general agreement that the immediate origin of DM1 in families is incremental, with the disorder evolving gradually in successive generations across a threshold of repeat size producing clinical abnormalities.

Turning to the ultimate origin of the mutation, the situation is entirely different. Family and population studies in widely different countries, especially isolates or founding populations, such as those conducted in Quebec, northern Sweden, South Africa and Istria, had already shown an origin of the disease from one or very few ancestors—which is a conclusion supported by genetic marker studies. The discovery of linkage disequilibrium in more mixed populations (116) suggested that origin of the disease worldwide might be from a small number of ancestors. This view is supported by the finding that the DM1 expansion is not only the basis of the disorder worldwide but is exclusively associated with one allele of an insertion deletion polymorphism at this genetic locus.

Studies of the distribution of normal repeat sizes at the DM1 locus in different populations have shown considerable differences. It has been suggested that the frequency and origins of the DM1 mutation in a population might be related to such distributions, possibly with a higher frequency of larger sizes predisposing to a high

frequency. It has been shown that the haplotype associated with DM1 is also that found most commonly in individuals with a repeat number of five, together with those less common individuals showing repeat number in the upper range, but not those in the intervening range of repeat numbers. This has led to the hypothesis that the original mutational event was a jump from a repeat number of five to some value in the upper range, rather than a gradual increase through the intervening range (117). The shared worldwide haplotype indicates that this could have been a unique event (118), rather than the occurrence of a predisposition to instability on multiple occasions. This view has been challenged in the light of more general population studies of the distribution of CTG repeat lengths, suggesting that the occurrence of a group with high repeat numbers may antedate the origin of the insertion deletion polymorphism (119).

The geographic variations in current prevalence of DM1 are relevant to these questions. Although most differences can be attributed to relatively recent founder effect or to thoroughness of ascertainment, there is a striking absence of the disease in sub-Saharan African populations, even when carefully studied (120). This could reflect the different normal pattern of repeat sizes (121), in particular a relative deficiency of high repeat number alleles. It could also be due to the original mutation for DM1 having occurred after the divergence of African from Oriental and Caucasoid populations. The resolution of this question will be of considerable interest from a general anthropological angle, as well as for DM1. The re-evaluation (122) of a Nigerian patient, originally reported by Dada et al. (123), showing a CTG expansion on a different haplotype, is of considerable interest. In eastern (Asian) Indians patients with DM1, expanded CTG repeats have been found in yet another haplotype background, which is uniquely prevalent among the Indian population (124). The exceptional nature of these cases does not itself disprove a single origin of the mutation over most of the world. An issue that has repeatedly arisen in discussion of the origin and spread of DM1 is why, if its mutational origin has been so restricted and its subsequent effects in established cases are so deleterious, it has persisted as a relatively common disorder. In part, this is likely to be because of the considerable pool of normal individuals with repeat sizes near the upper limit of normal, who can act as a reservoir for the future origin of new cases through genetic instability, a process now validated in a recent study of premutations (79). In this context, the expansion into the upper range of normal repeat size, instead of the expansion into the lower abnormal range, must be considered the original mutational event of DM1 that took place after the migration out of Africa.

It is also possible, however, that additional factors are operating, one of which has been suggested to be “meiotic drive,” which is the term given to the preferential transmission at meiosis of a particular allele at a

given locus. Evidence for this has now been put forward in two studies, with preferential transmission in normal individuals of the chromosome carrying the larger repeat size at the DM1 locus (125,126). The data are inconsistent in regard to sex of transmitting parent, and reanalysis has not shown any evidence for abnormal segregation. Similar suggestions for an abnormal segregation of the expanded allele in DM1 families (83,127,128) and in transgenic mouse lines (107) have been reported; however, data from prenatal molecular studies, which are not subject to ascertainment bias, showed no evidence of meiotic drive (129).

The prevalence of the disorder in relation to other muscular dystrophies warrants mention. If the exceptionally high frequency in some isolated populations and the apparent deficiency in those of African origin are ignored, a range of estimates of 2.5–13.5 per 100,000 has been obtained in a series of European studies (summarized by Harper (130)). Given the difficulties of complete ascertainment, this suggests a broad prevalence for clinically significant cases of around one in 10,000, a higher figure than for other autosomal dystrophies, and comparable to that of Duchenne muscular dystrophy in prevalence, although lower in incidence. To explain the high prevalence of DM1, it now seems clear that the source of new cases lies principally in those clinically normal individuals with subclinical expansion in the gene, not in individuals with cataract or other mild clinical features where inter-generational disease transmission is self-limiting because of the severity of anticipation.

### 130.4.2 Genetics of Myotonic Dystrophy Type 2 (Proximal Myotonic Myopathy)

The clinical phenotype of DM2/PROMM closely resembles that of DM1. The identification of the DM2 mutation indicated that the genetic mutations are similar in these two disorders, in that both are caused by large expansions of an unstable repeat that contains transcribed but untranslated CUGs. The DM2 CCTG repeat varies in copy number in the general population, ranging from approximately 10–30 repeats. The range observed in patients is much larger than in DM1, spanning from 75 to more than 11,000 repeats, with an average of approximately 500 (54,59). Subsequent studies have suggested that DM2 shares at least a part of the pathogenic mechanism of DM1, such that the mutation exerts a *trans*-dominant RNA gain-of-function. The clinical and molecular genetics of DM2 have demonstrated some important distinctions. Anticipation has been described (59,131), but is not striking. Neither severe congenital form of DM2 nor obvious parental origin effects have been identified. Nonetheless, the DM2 repeat shows a high degree of intergenerational repeat-size instability with a tendency for contraction, striking somatic repeat-size mosaicism, and rapid expansions throughout the lifetime of the individual (54,59). The most consistent

correlation with repeat size was the age of the patient at the time of blood sampling. These very high levels of instability may have hampered attempts to analyze an intergenerational bias, parental origin effects, and the correlation between the repeat size and the age of onset.

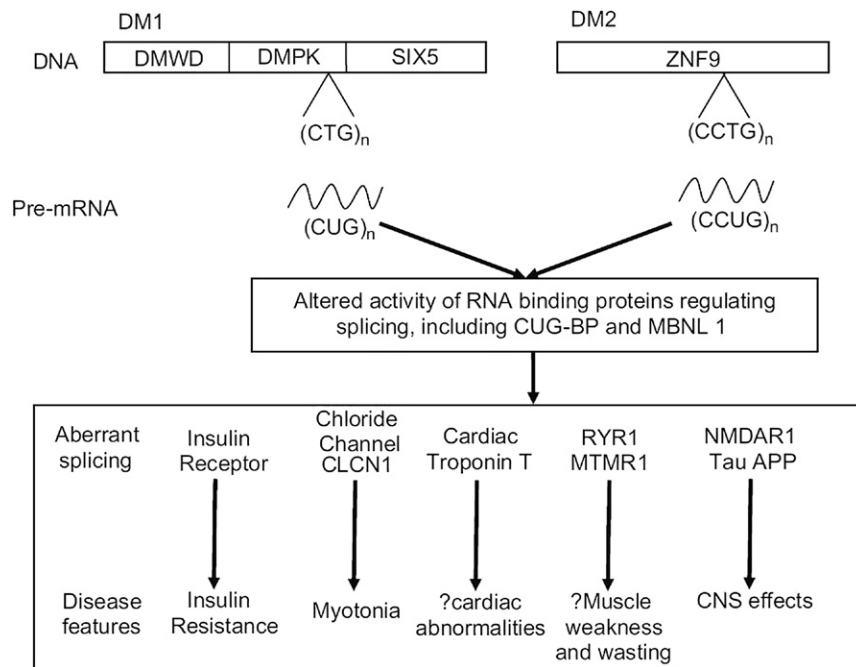

All DM2 families identified to date are from northern Europe, primarily Germany and Poland as well as American families with ancestors from these regions (59). An Afghan family has been described (61,132). The DM2 mutation has not been identified in sub-Saharan or east-Asian populations. The prevalence of the DM2 mutation in Germany has been estimated to be at least 1/100,000 (133). Recent haplotype and linkage-disequilibrium analyses of these families suggested that the DM2 expansion originated from a single or a few founder mutations (132,134). These studies estimated that the DM2 expansion mutation has arisen 200 to 540 generations ago (134), possibly before the Aryan migration of Indo-Europeans (132).

## 130.5 MOLECULAR AND CELL BIOLOGY

### 130.5.1 Molecular Pathogenesis of Myotonic Dystrophy Type 1

The mechanism through which the expanded CTG repeat leads to the multisystemic clinical phenotype of DM1 is still under investigation. The CTG repeat is located in the 3' untranslated region (3'UTR) of the *DMPK* gene and therefore the coding information of this gene remains intact in the mutant *DMPK* gene. The CTG repeat is transcribed into the messenger RNA (mRNA) as an identically sized CUG repeat. Although mechanisms of the majority of genetic diseases involve alterations of the protein product, this appears not to be so in DM1 and 2. The expanded CTG repeat gives rise to a mutant *DMPK* mRNA that contains an abnormally elongated CUG repeat. The expanded CTG repeat may also affect the mRNA levels of neighboring genes and the *DMPK* gene. Three major models of disease mechanism have emerged for DM1: (1) a model based on a gain of toxic function by the expanded CUG repeat in the mutant *DMPK* mRNA, (2) a model based on the loss-of-function of the genes in the vicinity of the CTG repeat, including *DMWD*, *SIX5*, and *DMPK* itself (Figure 130-8) and (3) haploinsufficiency of the *DMPK* protein, although there is little evidence for this hypothesis. The evidence for a toxic gain-of-function has been most compelling in recent years.

**130.5.1.1 Gain-of-Function by the Mutant *DMPK* mRNA.** DM1 is an autosomal dominant disease and therefore, even if the expanded CTG repeat totally suppressed the expression the *DMPK* protein from the mutant gene, the *DMPK* protein would still be produced at 50% of the usual level from the normal allele. For most genes, 50% is a sufficient amount to support normal cell functions. If the mutant *DMPK* gene makes

**FIGURE 130-8** Summary of the molecular pathogenesis of myotonic dystrophy type 1 (DM1) and myotonic dystrophy type 2 (DM2), a “spliceopathy.” (Adapted from Turner and Hilton-Jones (4).)

a toxic product, it can produce cellular dysfunction regardless of the level of the normal DMPK protein. Therefore, a gain-of-function is an attractive pathogenic model to explain the dominant inheritance of DM1. The CTG repeat is located in the 3'UTR and therefore the gain-of-function model would not work for DM1 through the DMPK protein; however, the expanded CTG repeat is transcribed into the mutant DMPK mRNA as a noncoding CUG repeat, making the RNA-based gain-of-function most plausible. The first observation to support such an RNA gain-of-function model was that the mutant DMPK mRNA accumulates in nuclear foci in DM1 cells (135). Krahe and coworkers (136) postulated that abnormal processing of the mutant DMPK mRNA could be the basis of the gain-of-function theory in DM1 (see Figure 130-8).

Experimental evidence to support this hypothesis came from cell culture models. Mouse C2C12 myoblasts that express a transgene with expanded CTG repeats in the 3'UTR showed most of the characteristics of molecular pathology seen in DM1, including nuclear retention of the transgene mRNA and inhibition of myoblast fusion and differentiation (137–139).

Timchenko et al. (140) identified CUG-binding proteins (CUG-BPs) that bind to the 3'UTR of DMPK mRNA and CUG-BPs accumulated in muscle of a DM1 patient (141). Subsequently, CUG-BP was shown to regulate splicing of cardiac troponin T (*cTNT*) (142), insulin receptor (*IR*) (143), muscle chloride channel (*CLC-1*) (144,145), and myotubularin-related 1 (*MTMR1*) (146) gene transcripts, and splicing of these transcripts is altered in the muscle from patients with DM1. Furthermore, CUG-BP was shown to target *C/EBP* beta, which

regulates expression of many genes, and DM1 muscles show increased translation of an inhibitory isoform of *C/EBP* beta (145). CUG-BP appears to be involved in splicing regulation of many other gene transcripts that contain the “UG” repeat motif in the targeted intron (147). It was postulated that splicing abnormalities could lead to altered proportions of normally occurring isoforms or the production of aberrant isoforms. Widespread splicing dysregulation of mRNA from many genes, mediated through dysfunction of splicing factors such as CUG-BP, may therefore cause the multisystemic abnormalities of DM1. Since this suggestion, a group of other neurological diseases with a similar postulated mechanism have been described and named the “spliceopathies” (148).

Soon after the discovery of CUG-BP, it became clear that there are other CUG repeat binding proteins, which have been named CELF proteins (147). Miller et al. (149) identified a different class of proteins designated triplet repeat expansion (EXP) RNA-binding proteins. *Muscle-blind*, the *Drosophila* homolog of EXP, is required for terminal differentiation of skeletal muscle and eye, and EXP is expressed during muscle differentiation in mice. In humans, the EXP proteins consist of three paralogs (MBNL1, MBNL2, and MBNL3) coded by different genes on chromosomes 3, 13, and X, respectively (150). In contrast to CUG-BP, which binds to single-stranded CUG's, EXP binds to double-stranded CUG repeats, which are generated when CUG repeats form a hairpin structure (149). A longer CUG repeat tract is more likely to form a double-strand hairpin, and the EXP binding increases when the CUG repeat tract is longer. A study using yeast-three-hybrid analysis showed that MBNL1 interacts with both CUG and CCUG repeats, whereas

these repeats are not the primary targets of CUG-BP (151). Furthermore, the EXP proteins, but not CUG-BP, are detectable in nuclear foci in DM1 muscle, myoblasts, and fibroblasts, where the mutant DMPK mRNA is accumulated (150,152,153). MBNL1 has been found to be an important determinant of nuclear foci formation and aberrant IR splicing in DM1 (154), whereas CUG-BP and other CELF proteins regulate the equilibrium of splice-site selection by antagonizing the facilitatory activity of EXP proteins on splicing of IR and cTNT (154,155). The authors also showed that CUG-BP levels were elevated in DM1 cells by mechanisms that were independent of MBNL1 and MBNL2 loss.

In DM1 brain, cortical and subcortical neurons also show nuclear foci of mutant RNA, sequestration of EXP proteins, and dysregulated alternative splicing (156). In brains of patients with DM1 and of mice transgenic for the human myotonic dystrophy region with expanded CTG repeats, tau, a protein that is involved in many neurodegenerative diseases, shows abnormal isoforms that aggregate (31,157). Alternative splicing of the NMDA-R1 may also cause some of the functional neurological affects observed in DM1 (156). The SLITRK proteins are expressed primarily in neural tissue and have been implicated in affecting neurite outgrowth. Recently, reduced expression levels of SLITRK 2 and 4 have been described in adult and fetal post-mortem brain and in motor neurons differentiated from mutant DMPK human embryonic stem cells. These cells also demonstrated reduced synaptogenesis and increased neuritogenesis (158). These studies suggest that the RNA gain-of-function also contributes to the CNS pathophysiology in patients with DM1.

The gain-of-function mechanism mediated by the mutant DMPK mRNA through binding of these proteins to the expanded CUG repeat could explain both the dominant inheritance and multisystemic nature of this disease. Studies of two genetic mouse models have provided convincing evidence that this mechanism plays a central role in the pathogenic mechanism of DM1. First, Mankodi and coworkers (159) established a transgenic mouse line that expresses the skeletal actin gene engineered to include an expanded CUG repeat tract in the 3'UTR. The phenotype in these mice consisted of robust electrical myotonia and clinical and histopathological features of myopathy, very similar to those seen in human DM1. Furthermore, these transgenic mice showed the abnormal splicing pattern of muscle chloride channel, *Clcn1* gene in a pattern similar to that seen in human DM1 muscle (144,145). Second, disruption of the mouse *Mbnl1* gene leads to muscle and eye phenotypes, and RNA splicing abnormalities that are characteristic of DM1 (160). A summary of the changes in mRNA splicing which have been described in skeletal muscle, cardiac muscle and brain are detailed in Table 130-11 (adapted from 147). The toxic gain-of-function of mutant DMPK mRNA may be mediated by toxic effects other than the

mis-splicing of pre-mRNA. There is recent evidence of RNA transcriptional effects with NKX2-5 (161). Post-transcriptional effects may also occur since CUGBP1 has been shown to play a role in RNA stability (162).

The molecular mechanisms causing muscle wasting in DM1 are poorly understood. The aberrant expression of the ryanodine receptor (*RyR1*) with exon 70 exclusion in adult DM1 skeletal muscle may alter excitation-contraction coupling and promote muscle degeneration (163). A mouse model expressing expanded CTG repeats in the 3'UTR of *DMPK* has been demonstrated to develop a muscle wasting phenotype that was temporally correlated with increased CUGBP1 expression, suggesting that CUGBP1 may contribute to muscle wasting in DM1 (164). A DM1 mouse model with skeletal muscle over-expression of CUGBP1 has been shown to reproduce many clinical and molecular defects of DM1 muscle including muscle wasting and dystrophic histology, which has added support for the hypothesis linking increased CUGBP and dystrophy (165). This has not explained the mechanism by which mis-splicing causes muscle loss. It has recently been demonstrated that elevated MBNL-3 levels disrupts Myocyte Enhancer Factor

2 (Mef2)  $\beta$ -Exon Splicing and this is a potential mechanism contributing to myodegeneration in DM1 (166).

**130.5.1.2 Loss of Dystrophia Myotonica Protein Kinase Function.** Although loss-of-function theories are less attractive than a gain-of-function to explain autosomal dominant diseases, there are autosomal dominant diseases caused by “haplo-insufficiency.” Thus, DMPK deficiency was proposed as the first pathogenic model soon after the identification of the DM1 mutation. However, studies have reported conflicting results regarding DMPK mRNA levels in skeletal muscle and other tissues from patients with DM1. Most studies, especially those using adult DM1 tissues, showed decreased levels of DMPK mRNA (reviewed in Reference (76)). The decrease in the DMPK mRNA has been correlated with the size of CTG repeat expansion, and attributed to the retention of mutant DMPK transcripts in nuclear foci in DM1 cells rather than impaired transcription of the mutant *DMPK* gene (see Figure 130-8) (136,167–169). Furthermore, Wang et al. (170) found that actual DMPK mRNA levels are below 50% of the normal level in some patients with DM1, potentially by dominant negative effect of the mutant DMPK mRNA on the wild-type DMPK mRNA.

DMPK is one of the myotonic dystrophy family of protein kinases (MDFPK). Although DMPK mRNA is strongly expressed in skeletal muscle, heart, brain, liver, and kidney (169), its exact physiological function is not fully understood. DMPK phosphorylates serine and threonine residues of myosin-binding subunit of myosin phosphatase and inhibits myosin phosphatase activity (171). Thus, DMPK may be involved in regulating cell size and shape like other MDPK. Several other proteins, such as the  $\beta$ -subunit of the L-type calcium channel (172), phospholemman (173), and CUG-BP (141) are also phosphorylated by DMPK. The DMPK protein appears to be preferentially localized in muscle and heart (174). In skeletal muscle, the DMPK protein has been found in sarcoplasmic reticulum (175).

The DMPK loss-of-function hypothesis came into focus in 1996, when initial observations of DMPK-deficient mice showed no robust abnormalities (176,177) except for mild muscle weakness. Further studies of homozygous and heterozygous *DMPK*-deficient mice suggested that haplo-insufficiency of DMPK does cause skeletal and cardiac muscle abnormalities through alterations of sodium and calcium channels. The abnormal sodium channel opening and repetitive discharges observed in the skeletal muscle membrane of these *DMPK*-deficient mice (178) may be in part caused by silencing of muscle Na channels (179). Skeletal muscle cells derived from *DMPK*-deficient mice also showed abnormal conductance of dihydropyridine receptor (180), which colocalized with DMPK at the sarcoplasmic reticulum (175) and was phosphorylated by DMPK in vitro (172). Cardiac conduction block found in homozygous and heterozygous *DMPK*-deficient mice (181,182) may be attributable to abnormal sodium channel gating

(183). Single cardiomyocytes derived from *DMPK*-deficient mice showed enhanced basal contractility, with evidence suggesting that increased  $\text{Ca}^{2+}$  uptake into the sarcoplasmic reticulum is the underlying cause (184). Thus, *DMPK* haploinsufficiency could account for some electrophysiological abnormalities in DM1 skeletal and cardiac muscles.

The *DMPK* isoforms may add an additional twist to the haploinsufficiency theory. Alternative splicing of *DMPK* transcript in a transgenic mouse model produces six major isoforms, with tissue-dependent expression (185). *DMPK* isoforms have cell-type- and subcellular location-dependent substrate specificities, which are attributable to an alternatively spliced VSGGG motif and C-terminal structures (186). Four RNA splicing factors have been shown to bind the *DMPK* transcript at the 3'UTR region downstream of the CUG repeat, yielding a novel mRNA isoform containing no CUG repeats, which was not retained in the nucleus in DM1 cells (187). Further studies are needed to gain additional insights regarding the role of these isoforms in the *DMPK* haploinsufficiency hypothesis.

**130.5.1.3 Effects on Adjacent Genes.** The CTG repeat expansion affects the chromatin structure and the expression of *DMPK* and neighboring genes, *SIX5* and *DMWD* (see Figure 130-8), in myotonic dystrophy. DNA triplet repeats mediate heterochromatin-protein-1-sensitive variegated gene silencing (188).

**130.5.1.3.1 Loss of *SIX5* Function.** *SIX5*, previously known as DM associated homeodomain protein (*DMAHP*) (189) is located immediately downstream of the *DMPK* gene (see Figure 130-8). *SIX5* shows homology to the *Drosophila* gene *sine oculis* and is involved in muscle and gonad development (133,190). Wang et al. noted that a DNase I sensitive site positioned immediately downstream to the CTG repeat is eliminated when the CTG repeat is expanded, and attributed this sensitivity loss to tight binding of nucleosomes to expanded CTG repeats (170). Thus, an expansion of the CTG repeat might impede the RNA polymerase procession through chromatin or the accessibility of transcription factors for the neighboring gene. The *SIX5* mRNA is found in tissues affected in DM1 such as eyes, skeletal muscle, heart, and brain (189,191). Subsequently, it was found that an expansion of the CTG repeat reduces expression of the *SIX5* gene, by impeding an enhancer element for the *SIX5* gene (see Figure 130-8) (192–194). This effect is expansion size-dependent and tissue-specific, with the greatest reductions found in muscle and liver (194,195). In contrast to these results, however, other groups reported no significant reduction in the *SIX5* expression level in DM1 tissues (196,197).

Klesert et al. (198) and Sarkar et al. (199) independently showed that *SIX5* deficiency causes cataracts in both homozygous and heterozygous “knockout” mice. *SIX5* regulates the transcription of the Na, K-ATPase 1 subunit gene (*Atpla1*), and the increased *Atpla1* mRNA

level in *SIX5* deficiency may alter the regulation of the osmotic balance within the lens and contribute to the development of lens opacity (199). Cardiac conduction system abnormalities were also found in *SIX5*-deficient mice (200). However, *SIX5*-deficient mice do not exhibit histopathological, contractile, or electrophysiological abnormalities in the skeletal muscle (201,202). Further studies are needed to determine whether other organs show abnormalities compatible with DM1 in these 'knockout' mice.

**130.5.1.3.2 Loss of DMWD Function.** An expansion of the CTG repeat may also influence the expression of the immediately upstream gene *DMWD* (see Figure 130-8) (203). The 5' end of the *DMPK* gene overlaps with the 3' end of the *DMWD* gene, and the 3' boundary of the *DMWD* has not been clearly defined. *DMWD* is highly expressed in brain and testis, which are known to be affected in DM1. The predicted protein product contains WD repeat sequences, which are found in several proteins engaged in control of cell division, transcription, mRNA processing, cytoskeletal assembly, vesicle fusion, and signal transduction (204). Decreased *DMWD* mRNA levels were reported in the cytoplasm of DM cell lines and adult DM1 skeletal muscle samples (203).

## 130.5.2 Molecular Pathogenesis of Myotonic Dystrophy Type 2

Mirroring the CTG repeat in *DMPK*, the CCTG tetranucleotide repeat in the first intron of the *ZNF9* gene (54) is transcribed into a CCUG repeat in the RNA but is not translated into the protein. The normal function of the *ZNF9* protein is unknown, although it is known to be capable of binding both DNA and RNA (205). No data have been reported on the transcription of the *ZNF9* gene from the mutant chromosome in DM2 patients. Therefore, whether haploinsufficiency of *ZNF9* plays any pathogenic role in DM2 remains unknown.

In addition to similarities in clinical phenotypes, significant similarities between DM1 and DM2 have also been demonstrated in the molecular mechanism of the disease at the RNA level (206). The muscleblind proteins accumulate in the ribonuclear foci containing CCUG repeats (151–153), and *CLC-1* and IR mis-splicing is also observed in patients with DM2 (145,207). These data suggest that the *trans*-dominant RNA gain-of-function mechanism may also have a central role in DM 2; however, one should be reminded that there are clinical differences between these two diseases, most notably the lack of the congenital form in DM2 (208). Whether the differences are due to the lack of loss-of-function of *DMWD/DMPK/SIX5* in DM2 or due to different gain-of-function effects by the CCUG repeat and/or loss-of-function of *ZNF9* remains to be investigated.

## 130.6 GENETIC COUNSELING AND RISK ESTIMATION

Genetic counseling for DM1 has always been difficult, owing to the extreme variability of the disorder, the parental origin effects, and the intergenerational differences. Although molecular advances have largely explained these phenomena, they have only partially helped in answering the practical questions. Approximate risk estimates based on the studies discussed earlier in this chapter are summarized in Tables 130-12 and 130-13. To a surprising extent, the guidelines remain based on premolecular work.

Full genetic counseling is particularly important in relation to presymptomatic testing (see later).

Although a full two-stage approach such as is generally used in Huntington's disease is probably required only in a minority of situations (209,210), presymptomatic testing is most certainly not a "laboratory only" procedure, and the complexities of genetic and family aspects require both time and experience. The International Myotonic Dystrophy Consortium (1) has established guidelines for genetic testing of DM1.

### 130.6.1 Molecular Analysis and Genetic Prediction

The feasibility of direct analysis for the DM1 mutation has become a routine approach to prediction and to genetic counseling in the disorder. Some of the tests for detecting minimal phenotype that were previously the mainstay of diagnostic testing, such as EMG and ocular slit-lamp examination, are obsolete. It is important to recognize that molecular analysis is also not without its pitfalls and inaccuracies, and that other evidence based on older tests should not be disregarded. The direct mutation analysis should also be used as the definitive diagnostic test for DM2 in prediction and genetic counseling.

In considering tests for prediction, several general points need to be borne in mind. First is the remarkable specificity and sensitivity of mutational testing in DM1 and DM2. If molecular analysis in an affected family member fails

**TABLE 130-12** Risk of Myotonic Dystrophy Type 1 for Clinically Normal First-Degree Relatives (Approximate)

Young Adults	10%	Risk of Carrying Mutation
(21–40)	5% Minimal	Risk of clinically significant disease Risk of congenitally affected child
Older adults (>40)	<5% >10%	Risk of clinically significant disease Risk of carrying mutation in sibship with cataract only
Children with congenitally affected sib	25% 10% 5%	Infancy Approximately age 16 Age >18

**TABLE 130-13 Risks to Offspring of Patients with Myotonic Dystrophy Type 1 (Approximate)<sup>a</sup>**

Parental Group	Approximate Risks to Offspring
<b>Men</b>	
Minimal disease, late-onset (usually <100 repeats)	No significant risk of congenital disease Risk of serious neuromuscular disease greater than offspring of corresponding females
Significant neuromuscular disease	Minimal risk of congenital disease Chance of reduced severity due to contraction of mutation greater than for female transmissions
Childhood onset	Reproduction rare. Congenital disease. Not expected
<b>Women</b>	
Minimal disease, late onset	No significant risk of congenital disease. Disease more likely to remain minimal (with unchanged repeat) than for male transmissions
Significant neuromuscular disease. Child already born with congenital onset	40–50% chance of congenital or severe childhood disease. Most of the remainder will remain unaffected
Significant neuromuscular disease. No congenitally affected child born	Uncertain. Chance of congenital or severe childhood disease 10–30% (see text)
Childhood onset	No systematic data, but chance of severe childhood disease high (probably 40–50%)

<sup>a</sup>NB: All groups have the same chance (50%) of offspring being genetically unaffected.

to show an abnormality, an alternative diagnosis is likely. On the other hand, if no such member is available, but the clinical diagnosis in the family is secure, molecular testing for DM1 and DM2 is still highly likely to give a definite answer. A second point, highly relevant for the laboratory, is the wide range of expansion that needs to be looked for in individuals who are homozygous for a normal allele on PCR-based analysis of DM1 and DM2 mutations. In DM1, Southern blot analysis is sufficient to supplement the PCR analysis, which may fail to amplify expanded allele. In DM2, however, the combination of routine PCR and Southern blot analyses is only 80% sensitive owing to the high degree of repeat size mosaicism. Additional repeat-primed PCR or long PCR should increase the detection of the DM2 mutation to 99% (59,211).

### 130.6.2 Prenatal Diagnosis

In DM2, no cases of prenatal DNA diagnosis have been reported, although it is technically feasible. This is probably because DM2 is generally presents as a milder disease than DM1, with no severe congenital or early childhood form. In contrast, prenatal diagnosis by direct mutation analysis is useful in DM1 families in which a severely affected child has been born, with a high risk of a subsequent child being similarly affected. The size of the expanded allele should be determined by Southern blot analysis, because repeat-primed PCR does not give the expansion size and long PCR may still have difficulty in amplifying very large alleles. Even extremely large bands are well defined on Southern blot analysis at this stage in DM1 fetuses (usually 10–12 weeks' gestation using chorion villus sampling) (103), reflecting the lack of somatic instability in early fetal life. The overlap between clinical groups makes it unwise to give

an accurate prognosis from the size of the expansion prenatally in DM1, although it is possible to distinguish the “minimal” phenotype from the severe in some cases. In any case, family studies alone have shown a close concordance in sibships once a severely affected child has been born (90).

When an affected man is the parent, a much greater range of expansion in the pregnancy is to be expected, with the possibility of reduction in size into the minimal, or rarely even into the normal range, as discussed earlier. The consequent uncertainty in likely severity needs to be made clear in genetic counseling beforehand.

Preimplantation diagnosis is now increasingly raised as a possibility for a range of genetic disorders, and there has been sufficient experience in DM1 to demonstrate it as an effective technique (212,213).

Although there is no evidence that pregnancy itself causes deterioration, it is important to recognize the possibility of complications during cesarean or other surgery and associated anesthesia. It is also important to discuss with patients that prenatal testing should not be performed if termination of the pregnancy is not considered as an option.

### 130.6.3 Presymptomatic Testing and Carrier Detection

Before undertaking presymptomatic testing and carrier detection, it is important to be clear as to what question is being asked. Is it related to the possible development of future disease (presymptomatic testing), to assessment of present symptoms in relation to the family disorder (diagnostic testing), or to concerns that the disorder might be transmitted in the absence of symptoms (carrier detection)? The answers to these questions will determine the

best combination of tests to be used. A symptomatic or asymptomatic young adult would be best offered genetic testing. In a young child at risk of DM1, clinical assessment remains the most helpful procedure, since genetic analysis in such a normal child raises many issues that may best be resolved when the child is older. There is no evidence that clinically normal mutation carriers are at any risk of surgical or other procedures.

A normal molecular result in an asymptomatic adult at risk now allows a high degree of reassurance in terms of both that individual's lack of risk of developing DM1 in the future and of transmitting the disorder (214), although confirmation of the mutation in an affected family member is always wise. This is a great advance on previous uncertainty resulting from the interpretation of lens-opacities and EMG, and from the possibility of recombination when linked DNA markers were being used. The uncertainty has now shifted to the prognosis for those who are clinically normal but shown to have an expanded repeat sequence. The correlations of phenotype available from current studies are retrospective and show broad variation; therefore any prognosis needs to be very cautious. For the "prematuration" expansion (38–49 copies), one can be reasonably confident that this will imply lack of significant neuromuscular disease, whereas the study by Gennarelli and coworkers (77) suggests that this can be extended to those with less than 100 repeats. Recently a comprehensive assessment of patients with less than 200 CTG repeats found that those with less than 100 repeats often only develop cataracts (215), although patients with symptomatic DM1 associated with less than 100 repeats can be seen. The psychosocial impact of presymptomatic DM1 testing was minor, although life is perceived as a change for the better by noncarriers and as a change for the worse by carriers (216). Presymptomatic testing is now feasible but no cases have been reported in DM2.

#### 130.6.4 Diagnostic Molecular Testing

The specificity of mutation testing now makes it extremely useful in assessing not only relatives with symptoms possibly related to the disorder but also those with no clear family history for whom DM1 or DM2 is suspected on clinical grounds. The differential diagnosis of congenital DM1, which is often difficult in relation to other neuromuscular disorders, is one such situation, whereas distinction of DM1 and DM2 from other myotonic disorders is easier in later life. The recognition of characteristic cataracts is a further situation in which molecular testing can be helpful.

As genetic testing is increasingly becoming a part of clinical practice, it is important that the genetic considerations be recognized and discussed with the patient to avoid problems. In this respect, DM1 and DM2 share many such issues with other late-onset disorders for which molecular testing is becoming an integral part

of practice and no longer the specialized preserve of geneticists.

### 130.7 MANAGEMENT

In spite of the profound changes in our understanding of DM during the past few years, we still have no specific therapy to alter the underlying course of the disorder. For the first time, however, we can look ahead to rational therapeutic approaches based on the relationship between the molecular defect and the pathological changes associated with the disease. As we discussed in the previous section, recent studies have shown increasingly convincing evidence for the trans-dominant RNA gain-of-function as the main pathogenic mechanism of DM1 and DM2. Experimental therapies using antisense oligonucleotides and ribozymes to counteract the RNA gain-of-function have been studied in cell culture and transgenic mice (217–220), and use of these strategies in human patients may become feasible in the future. Better understanding of the mechanism of the repeat instability may lead to the development of treatments to reduce the repeat size in patients (221,222). More recently, encouraging results using small molecules and antisense treatment has been published. Mulders (223) and Warf (224) have demonstrated reductions in ribonuclear foci and mRNA splicing defects using antisense oligonucleotides and small molecules in vitro and in animal models of DM1 by the complete elimination of expanded (CUG)*n* RNA transcripts or by the prevention of detrimental protein binding to thermodynamically stable (C/CUG)*n* hairpin structures. These developments offer new hope to patients with DM although obstacles such as toxicity and tissue-specific availability need to be overcome before small molecule and antisense treatments can be introduced into clinical practice (225).

There are several drug treatments for symptomatic management of DM1. The treatment of myotonia in DM1 is often not seen as a priority in the patient's management although there are probably a significant number of, especially younger, patients with otherwise minimal symptoms in whom treatment of myotonia could improve quality of life. Logigian (226) recently performed two randomized, double-blind, placebo-controlled crossover trials in 20 DM1 patients and found that mexiletine up to 200 mg 3 times daily was effective, safe, and well tolerated over 7 weeks as an anti-myotonia treatment. Phenytoin and quinine may also be helpful. The teratogenic possibilities for phenytoin and the cardiac conduction effects of all of these agents must be considered. Modafinil is useful in treatment of excessive daytime sleepiness (227,228). Bowel symptoms are often troublesome and may be helped with antibiotic treatment, such as norfloxacin, or a bile salt sequestrant such as cholestyramine (7,8).

Regular surveillance for cardiac conduction defects and tachyarrhythmias is important and a yearly ECG

should be performed as a minimum but there may be a role for electrophysiological testing in determining those patients who are most at risk.

The avoidance of unnecessary surgical and anesthetic hazards is vital. Unfortunately, many patients still experience avoidable post-operative complications. Mildly affected individuals with little physical disability are probably at greatest risk because the dangers are unappreciated. Conversely, helpful but necessary surgical measures, such as cataract extraction and correction of foot deformities, should not be withheld simply on the grounds of possible surgical hazard.

Major mobility aids, such as wheelchairs, are not needed by many patients or, if they are, only at a late stage, but thorough assessment of disability needs is important to avoid loss of mobility and independence. Light plastic ankle-foot orthoses to correct foot drop may make a considerable difference to stability and mobility.

The possibility of aspiration pneumonia resulting from swallowing dysfunction is possibly one of the most important complications of DM1. Regular assessment and advice by a speech and language therapist is important in conjunction with monitoring of vital capacity and sleep-disordered breathing with a home sleep study in the first instance. Many end-stage patients are malnourished, and discussion of possible parenteral feeding needs to be discussed earlier than is currently practiced.

Surveillance of patients should be an active process at each clinic visit and guidelines are being drawn up (4,229).

Finally, the importance of giving patients and families full details regarding their condition should not be underestimated. As with many genetic disorders, an informed patient is likely to know more about his or her own problem than most of the doctors and other professionals that they may encounter. Full written information produced in an easily readable style is probably the best way of ensuring that patients avoid most predictable complications of the disease. Helpful information of this type is available from the Myotonic Dystrophy Support Group and Muscular Dystrophy Campaign in the United Kingdom, from the Muscular Dystrophy Association of America, and from the Association Française contre les Myopathies in France, among others. A remarkable amount of information is also available on the Internet, but the sheer volume and its unselected nature are likely to give problems in interpreting the details. These issues have extensively been reviewed in the book “*Myotonic dystrophy: present management, future therapy*” (64).
